IRA NELSON HOLLIS
PRESIDENT 1917
THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

THE JOURNAL OF

THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Volume 39 January 1917 Number 1

THE ANNUAL MEETING

THE thirty-seventh Annual Meeting of The American Society of Mechanical Engineers, held in the Engineering Societies Building, New York, December 5 to 8, 1916, was the successful culmination of a year conspicuous in the annals of the Society because of the remarkable growth and the broad development of the varied activities of the organization during that period.

Outstanding features of the meeting were the record attendance, the unusually complete program arranged by the Committee on Meetings, and the spirit of coöperation which pervaded the whole proceedings and which rendered this meeting the most democratic which the Society has held.

The total registration was 1868, of which 953 were members and 915 were guests; the registration of members represented one in every eight in the entire membership. The total registration exceeded that of last year by 431 and showed an attendance from all sections of the United States.

This year, for the first time, as a result of the alterations and improvements in the Engineering Societies Building, it was possible to hold all the professional and social events of the meeting in the building. The social functions were simple in their nature, there was no charge for any of them, and the attendance was correspondingly large and representative. This situation served more than anything else to offset the usual conditions at big conventions that those who attend do not have a chance to get well acquainted. This feature of acquaintanceship, the encouragement of which has been one of the main purposes of the Annual Meetings, has now been developed to a degree which makes attendance at these gatherings immeasurably worth while.

> *"We have a duty clearly laid before us by William James when he writes, 'The martial type of character can be bred without war. Strenuous honor and disinterestedness abound elsewhere and we should all feel some degree of it imperative if we were conscious of our work as an obligatory service to the state.'*
>
> *"That is our motto and that is what we must strive toward during the coming year and for all time, as we must pass on into the higher atmosphere of goodwill, service and co-operation in order that our profession may take its place alongside of the science of Preventive Medicine, as one of the two constructive agencies in human life. It will not be enough that we remain simply conscious of the high mission of our profession. We must serve as soldiers of peace in a country prepared to defend its homes."*
>
> *IRA N. HOLLIS, in accepting the Presidency of The American Society of Mechanical Engineers.*

As expressed by E. J. Prindle, Chairman of the Entertainment Committee, in presiding at the smoker on Wednesday evening of the Annual Meeting, everyone was requested to "consider that the fellow on your right hand is modest and would like to know you; and that the fellow on your left hand is interesting and well worth talking to." This sentiment admirably voices the evident feelings of those who came to the convention and is one to which all apparently responded in the most cordial manner.

As at recent meetings, there were delegates from most of the local Sections, sixteen of the twenty being represented at this meeting. Several conferences of these delegates were held, which were productive of numerous suggestions that will be helpful to the Sections and to the Society generally. More and more, the influence of the local Sections is being felt. They already play a major part in the conduct of the Society. They are representative of the Society's membership, covering as they do the whole expanse of the country. They include all shades of opinion. Because of these strong local affiliations they are influential factors in their communities, and are developing coöperation in the engineering profession.

A wealth of experience was contributed at the twelve professional sessions held during the meeting, at which 36 papers were presented. Several of these sessions were in charge of committees or sub-committees and five of the papers were contributed by local Sections, having previously been read at Section meetings and because of their exceptional value assigned also to the Annual Meeting. Two committee reports were considered and the public hearings of the Boiler Code Committee continued the professional meetings until Saturday.

PRESIDENTIAL ADDRESS AND ELECTION

The meeting was opened on Tuesday evening, December 5, in the auditorium of the Engineering Societies Building with the presidential address by Dr. D. S. Jacobus, on Education in Engineering. In his presentation of this subject, Dr. Jacobus analyzed, in the light of his twenty years' experience as a teacher of engineering subjects and his ten years' acquaintanceship with the practical side of the engineering profession, the fundamental requirements in education of an engineer and reviewed his own suggestions for attaining the best results. The full text of the address follows this brief introductory account of the convention.

After the address, the Tellers of Election of Officers reported the result of the balloting as follows:

Total Votes Cast	2261
Thrown out defective ballots	1
Valid ballots counted	2260
For President:	
IRA N. HOLLIS	2259
Scattering	1
For Vice-Presidents:	
CHARLES H. BENJAMIN	2253
ARTHUR M. GREENE, JR.	2253
CHARLES T. PLUNKETT	2255
Scattering	7
For Managers:	
ROBERT H. FERNALD	2256
WILLIAM B. GREGORY	2256
C. R. WEYMOUTH	2255
Scattering	1
For Treasurer:	
WILLIAM H. WILEY	2260

The newly-elected President, Dr. Ira N. Hollis, President of Worcester Polytechnic Institute, was escorted to the platform and in accepting his election spoke as follows:

"MR. PRESIDENT, I thank the Society for having elected me president to serve during the coming year. Entirely apart from the high honor which you have conferred upon me, I accept the office as a serious duty and as a great opportunity for service. That word alone expresses what should be the motive behind the actions of every citizen of our Republic and especially of every engineer who is charged with tasks involving the safety and well-being of his countrymen.

"This is not the occasion for a long address from me, but I cannot refrain from just a few words on what I conceive to be the fundamental relation of our profession to society. We have for years worked honestly as individuals who long for the success, comfort and beauty of every American city. Now, we are at the dawn of a consciousness of our place and our duty as an association in which every member is eager to coöperate with every other members to the greater glory of our country.

"There are two thoughts that lie in the subconsciousness of every engineer. They are brought out in one sentence of 'The World Set Free' by H. G. Wells, and in the whole tenor of an essay by William James on the 'Moral Equivalent of War.' In the first sentence of Mr. Wells' book, he expresses the underlying force that has made man a civilized, reasonable being. 'The history of mankind is the history of the attainment to external power'; that is, to the use of energy external to man's body. Somewhere behind every great human problem lies the work of the engineer. Our country is a perfect example of this in its evolution from a few colonies with imperfect means of communication into the United States of America. A history of the great inventions and the changes wrought by the applications of science will some day reveal the potent influence of our profession upon every department of national life. What made the great slaveholding states possible? The Cotton Gin. What, therefore, created the whole atmosphere of political discussion during sixty years of the nineteenth century and finally plunged us into a great war? The Cotton Gin. What again saved the Union and welded it into one country from coast to coast? The railroads. We can name few of the questions before Congress that do not in origin or in their solution depend in some way upon the engineer. That is the complete justification of Mr. Wells' statement and of our existence as a society of engineers.

"We have a duty clearly laid before us by William James when he writes, 'The martial type of character can be bred without war. Strenuous honor and disinterestedness abound elsewhere and we should all feel some degree of it imperative if we were conscious of our work as an obligatory service to the state.' That is our motto and that is what we must strive toward during the coming year and for all time, as we must pass on into the higher atmosphere of goodwill, service and coöperation in order that our profession may take its place alongside of the science of Preventive Medicine, as one of the two constructive agencies in human life. It will not be enough that we remain simply conscious of the high mission of our profession. We must serve as soldiers of peace in a country prepared to defend its homes."

The remarks of Dr. Hollis indicate that the efforts of the Society for the coming year will be in the direction of public service; or, as he expressed it, that the motto will be "service to the state."

The President's Reception, which followed the exercises in the auditorium, was held this year on the remodeled and spacious fifth floor of the building, the large halls of which are now connected by three doorways 12 ft. wide. The brilliantly illuminated rooms were most attractive with their decorations.

OUTLINE OF MEETING

As usual, the business meeting and first professional sessions occurred on Wednesday morning. At exactly 12.30 o'clock, the sessions were brought to a close in order to honor the memory of John E. Sweet, the beloved founder of the Society, whose keen personality and simplicity of manner will long endure in the minds of all who knew him. A most fitting address was made by one of his older friends, Past-President Worcester R. Warner, and brief remarks were also made by Capt. Robert W. Hunt and by Dean Albert W. Smith, of Sibley College. Mr. John H. Barr, one of "Sweet's Boys," presided.

On Wednesday afternoon no less than four varied sessions were held simultaneously. On Thursday, attention was concentrated on the subject of Industrial Valuation for which an all-day meeting had been arranged. No other sessions than this were held in the morning, but in the afternoon there was a well-attended meeting in charge of the Gas Power Sub-Committee.

Friday ended the professional sessions with meetings in charge of the Railroad Sub-Committee and the Boiler Code Committee, besides one Miscellaneous Session at which a remarkably strong paper was given by W. L. Cathcart on the Development of our Fleet and Naval Stations.

In the afternoon of Friday, the public hearing of the Boiler Code Committee began, which continued on Saturday. The work of this Committee is increasing in importance and effectiveness and its accomplishments bid fair to be among the most enduring works of the Society.

On Friday evening, many of the college men who had been in attendance, attended banquets of their own institutions and joined in what has become an annual event for the alumni of several of the colleges or universities which have engineering courses.

The success of this, the largest and in many respects the best Annual Meeting which the Society has ever held, is due to the untiring efforts of the many committees actually engaged in its conduct. The convention as a whole was in charge of the Committee on Meetings, H. L. Gantt, chairman; and the entertainment in charge of the New York Section Committee, H. R. Cobleigh, chairman, with E. J. Prindle as chairman of the sub-committee on entertainment. The President's Reception was under the direction of the House Committee, William N. Dickinson, chairman. The welfare of the ladies was carefully provided for by the Ladies' Committee, Mrs. Herbert Gray Torrey, chairman.

ENTERTAINMENT FEATURES

Many of the New York members willingly assisted in the reception of out-of-town members and in making everyone acquainted through the organization of the President's Reception and Acquaintanceship Committees. The excursions were planned by a committee for that purpose, J. H. Norris, chairman.

The plan, instituted last year, of a Smoker on Wednesday evening of the convention was again followed with unqualified success. Like most of the other social affairs, it was held on the fifth floor and it was attended by about 750 who enjoyed the evening to the fullest extent. In a talk upon his experiences during a trip to Europe since the beginning of hostilities, Frank B. Gilbreth had his audience with him from beginning to end and withal made comments upon the situation which deserved serious thought.

On Thursday evening, the members and their friends assembled in the auditorium to listen to the symposium which had been arranged by the New York Section Committee on the subject of Aviation. There were four prominent speakers. Following the lecture those who desired went to the fifth floor to participate in the dancing and refreshments were served there as well as on the eleventh floor in the Society's rooms. The whole affair, while in a marked contrast to the more elaborate functions which have heretofore been held at the Hotel Astor or elsewhere, was pleasing to all who attended because of its simplicity and the fact that the chief reason for attending was the opportunity which it gave to meet other friends of the Society, and their friends.

Excursions were arranged for Wednesday, Thursday and Friday to several points of interest in New York and vicinity, and the plan, followed last year so successfully, of having comparatively few excursions, but trips of unusual interest, was again adopted. There were eight excursions, an account of which appears in the Society Affairs section of this number. Several of these were of interest to the ladies as well as to the men.

Not the least pleasing of the social occasions of the meeting was the tea served by the New York ladies in the Society's rooms on Wednesday afternoon, where at the close of the professional sessions many members were received.

PUBLICATION OF PAPERS

Most of the papers presented at the Annual Meeting have already appeared in the November and December issues of The Journal. In this issue will be found a comprehensive account of the discussion given at the various sessions and in the Society Affairs Section a further account of the entertainment features, excursions, etc. Papers which have not already appeared in The Journal will be published in comprehensive abstract form in early issues.

EDUCATION IN ENGINEERING

Presidential Address, 1916

By DR. D. S. JACOBUS

So much has been said and written of late about education that it might seem too worn a topic to bring before our Society, but having been a teacher of engineering subjects for over twenty years, and having for over ten years since that time been employed in what some are pleased to call the practical side of the engineering profession as distinguished from the teaching side, I feel qualified to pass judgment on certain features and trust you will bear with me if what I say seems more or less elementary.

Let us start with the professor—and let me say here that once a professor always a professor, provided one has felt the joy that goes with being in close touch with his students and in knowing that there is a mutual understanding and trust. Some are apt to class the professor as an impractical individual whose principal joy in life is to dream and idle away the long summer vacations, while others give him what is more nearly his just due. Let us look back on our own professors, those who taught us, and see what led to our respect and what qualities we would now regard as the most important. I feel sure most of us would not depart very far from the judgment of those who responded respecting the list which was prepared by the Carnegie Foundation for the Advancement of Teaching as the essential factors desirable in young engineers. The order of importance based on the replies received is as follows:

1 Character, integrity, responsibility, resourcefulness, initiative.
2 Judgment, common sense, scientific attitude, perspective.
3 Efficiency, thoroughness, accuracy, industry.
4 Understanding of men, executive ability.
5 Knowledge of the fundamentals of engineering science.
6 Technique of practice and of business.

As we grow older we see that the personality of the men more than any other quality left its lasting stamp, and that

Presented at the Annual Meeting, December, 1916, of The American Society of Mechanical Engineers, 29 West 39th Street, New York. Pamphlet copies may be obtained; price 10 cents to members, 20 cents to non-members.

it is this more than anything else that causes us to look back with kindness and affection to our college days. Character is the first on the Carnegie list, and this as well as many other qualities that are to an extent independent of the course of study precede those that relate to the technical side of the course. In the discussion of engineering education the details of the courses are apt to be given undue weight, which is a grave mistake. System can never take the place of personality, and a given course that would be a success when taught by the right men might be a failure if taught by others.

Let us analyze the factors in the Carnegie list. First of all it is apparent that most of them apply to any profession and that they are not limited to engineering. Again, it might appear that one should succeed in a profession if he possesses the first factors in the list, even though he may not possess those included in the last two items. It would be a dangerous conclusion for a young man to feel that his success is assured if he has character and the other qualities which come near the head of the list, and that it is not necessary for him to have thorough knowledge of the technique of his profession. Such an unfortunate would soon find that the ethical qualities alone will not earn his bread and butter, and that a lack of knowledge in his profession will be an immense handicap.

What are the particular elements that spell success for a young engineer in addition to the elements that are common to all professions? Dear Uncle John Fritz once said that he could tell whether a young lad would be apt to succeed by watching him unobserved when sweeping a sidewalk. Yes! and we will all agree that much depends on what is in the lad. Eckley B. Coxe talked with me earnestly in the good old days as to what he considered the failure of some colleges to secure the right timber in their graduates. He compared the ordinary system of examinations to riddling the men through a series of sieves and throwing out the unfortunate fellow who had peculiarities that made it impossible for him to pass through the mathematical or other sieve. Mr. Coxe was a firm believer that there is a "something" required in the making of an engineer which cannot be gaged by an ordinary examination, and I remember well that he told me he employed some highly paid men who did not know an integral sign from a dollar mark, and that he knew of others classed as the best of graduates he would rather pay high salaries to keep out of, than in, his organization. What is the "something?" What is it that the old-time superintendent has in mind as he shakes his head sadly when asked how some young graduate is progressing. The lad may have character, judgment, and perhaps everything in the Carnegie list, or at least he may think he has, and yet our old-time friend, often from the land of the heather, knows there is something lacking. And we ask again, what is this "something"?

Would that I could define the "something." It includes such qualities as:

Taking a personal interest in one's work
Amenability to discipline
Perseverance under adverse circumstances
Cheerfulness and amity—the human side.

None of these appear separately in the Carnegie list.

Let us analyze these qualities. It will be seen that possibly a lad from a grammar school would be as likely to possess them as the college man. If this is so, then there is a lack in this side of the college training, and it is here that we should improve. Consider the first: "Taking an interest in one's work." In this the college man often fails. I have known of cases where on being censured for lack of accuracy the college man said that he could not take enough interest in the work as it was not up to his capabilities and could be done by any office boy; and often a bright office boy would pass him. The young man to succeed must take such an interest in his work that he will take pride in doing it in the very best way, be it what it may. He should be determined to hang on until the finish. The man who has an engagement that calls him away when he is asked to help in an emergency, seldom wins. The practical foreman will often keep the young college man he is trying out on monotonous work to determine his staying powers. Industry is given as an essential in the Carnegie list, but the determination and staying powers that count for success include more than simple industry. The man must be more than industrious; he must not only work hard and continuously, but be so interested in his work that he feels a personal responsibility in it. Further, the "industry" should be of the sort that is not governed by the clock, but which calls for many nights of labor, either in home study or in the field. Success is the fruit of hard labor achieved through the building up of many things into a grand and harmonious whole. The Good Book speaks of time-servers and those who work from the heart; there is no better criterion to distinguish between one who will fail and one who should succeed.

The second is "amenability to discipline." There is a lesser importance assigned to this than there should be in other as well as in teaching lines. The old-time preceptor with his hickory rod or stout ruler was but carrying out the home discipline where the word *obey* carried its full force. Perhaps the wave will change to bring back the good features of the old *régime*,—let us hope so. We certainly can and are doing much in our colleges to teach respect for authority and obedience to rules, but we should do more; let us not overlook this most important part of an engineer's equipment, and emphasize the importance of his being governed by these principles in the field.

The third is "perseverance under adverse circumstances," and the fourth, "cheerfulness and amity." The most unfortunate frame of mind a young engineer can get into is to feel that everyone is against him and that his efforts are not appreciated. I have often told the young men that those who select them take a pride in seeing them succeed. Believing a thing is so may often make it so, therefore the young man should encourage cheerful beliefs. To succeed, one should make friends of those about him. There is no surer way of making a man an enemy than to mistrust him. Great things can as a rule be done only through coöperation, and in the broad analysis the human side has much to do with success. "Study your man as well as the job" is a good motto to follow, but with it should be coupled a perseverance and cheerfulness that will induce the man to study you.

In applying for a position the young graduate will often injure his cause by inquiring too minutely respecting the prospect of advancement. Again, after being employed he may have the idea that in view of his special training his work should be in line with developing this training and that he should be given a certain preference over an untrained man. Such an attitude is bound to lead to discontent and misunderstanding. I have advised graduates many times to "size up" their chances before applying for positions and not to talk prospects, and have further impressed on them that they must enter the outside world on an even basis with their co-workers, and that any advantages they secure through education must come through the ability this education gives them to do better work than the others.

Having thus briefly reviewed the qualities necessary in an

engineer, let us consider the student. How can we bring out those qualities which we all agree are the most important. Character can best be taught by example, and the teacher must serve as an inspiration and guide. To teach effectively one must be a master of his subject, and this applies particularly to those qualities placed near the head of the Carnegie list.

We hear and read much respecting teaching methods. Methods are not all: the spirit which unconsciously develops is a most vital factor. I cannot fail to observe that there has been a great change in one respect since I was a boy. In my school days a failure to acquire a subject was laid to the student; now there is a tendency to lay it to the teacher. Much of this is due to the attitude of the parents. A fond mother once told me she thought it strange that no teacher could be found capable of teaching her boy mathematics, not realizing that she herself might be the greatest stumbling block through transmitting the idea that the fault lay anywhere else than with her son. A way never has and never will be found to acquire knowledge without study, and much of the trouble experienced by some students arises through a lack of study or a failure to appreciate the fact that the fault is their own.

Where the teacher is often at fault is in his failure to train the lad to study in a proper way. To memorize is the lowest form of study, and much of our present system may be justly criticised in this respect. A certain amount of memorizing is essential to "train the mind," as those who taught us used to say, but there is much in the doctrine expressed by that lovable professor, John E. Sweet, in the words, "What is the use of teaching a man a mass of material he is bound to forget?" We should develop initiative and encourage originality, and this cannot be done through memorizing or through any fixed course. It is here that a teacher who is worthy of his calling excels one who takes the easiest way. There is an easiest way in teaching just as there is an easiest way in studying, and both spell lost time and lost opportunities. The easiest way in teaching is to follow a beaten course and rely on the recitations and routine examinations in grading the men. To preserve the standard it is appreciated that the weaker men should be weeded out, and by so regulating the course that the weaker men fall by the wayside it might appear that the brighter men will remain and that there will be a "survival of the fittest." Such a course is fraught with the gravest dangers, as some of the best men may be dropped or may leave through being discouraged, and the college, though it may do good to many, may also do untold harm. Again, those who remain and graduate may have highly trained memories with little initiative and power of reasoning. The right way is for the professor to know the individual characteristics of each of his students and to be governed by this in deciding a case. Often if he can get at the root of a special difficulty it can be cleared away and there will be no further trouble. Still, there are cases where the student does not have an aptitude or liking for engineering, and in such instances it is a kindness to start him in some other line of work.

To accomplish the best results the course should be so laid out that there will be the right amount of time for rest and recreation. The student should be encouraged to spend a proper amount of time in outdoor exercise. A healthy and clean body is indispensable for a healthy mind and is even more to be desired than a trained mind. Just as soon as a course becomes so crowded that there is no time for anything but work and study, it will lose in efficiency, as there will then be no time for daily relaxation of the mind and for properly developing initiative. To obtain the best results the student must work enthusiastically and cheerfully, and if the course is such that he is constantly on the anxious seat, his perspective will become shortened and he will work at a disadvantage. We should train the student to work in the same way that he should work after his graduation. It is often remarked that students working their way through college stand surprisingly well, considering the amount of time available for study. We all agree that the man who does this has determination that makes him bound to succeed, but it is this determination that leads to a proper method of study and the clearing of his mind through thinking at times of entirely different subjects than his studies that makes his brain keen and quick. The students should be encouraged to occupy their spare time in some congenial way; there is nothing better than a good, healthy fad. But, it is asked, how shall we know that the spare time is used to advantage, and would it not be best to completely fill every hour of the day and thus, as some have said, keep the boy out of mischief? It is here that the human side of the professor must be brought into play, and to properly apply this side he must know his pupil and know him well. The classes must not be so large that it is impossible to obtain the intimate personal relation which is indispensable.

Recitations and examinations should be so conducted as to bring out more than can be memorized and to take into account the widely varying factors of temperament. It is far easier to lead and have the students follow than to call for initiative and guide them back if they depart from the right path, but the easiest way results mainly in training the memory, whereas the other includes the developing of qualities that are most apt to lead to success.

To teach engineering efficiently the professor should have practical experience. Sometimes this is acquired before the professor begins his career as a teacher; in most cases, however, the professor undertakes practical work in connection with his college duties. To secure the best results where the professor undertakes practical engineering work, the roster should be so arranged that certain of the professors dealing with the more practical engineering lines are given latitude in meeting the classes. One must not be misled into the idea that if a certain latitude is provided it will be an easy matter for the professor to undertake this work. He will find that to accomplish results he must often work night after night, as well as through the vacation periods, and unless he is willing to do this it is folly for him to endeavor to gain practical experience and a reputation in this way.

There is no enterprise that will reflect more credit on a college than undertaking properly conducted experimental investigations, especially if those suitable for the purpose are made the basis of papers presented to engineering societies or published in the technical press. The making of experiments and the issuance of reports carry with them grave dangers, in that there may be a tendency to do work for which the professor has not the proper capacity, and reports may be made that will throw discredit on his college. A professor should not be permitted to endorse commodities where the idea is simply to obtain his name, or worse than this, his name in connection with his college, for use in advertising matter; nor should he allow his name to be used in tests which may be of more value to the promoter than to the engineering profession. Above all, he must be careful in his reports and in his testimony as an expert not to bring discredit to his profession and his college by departing a hair's-breadth from the truth or by testifying in a way which will evade the truth. There is danger in any enterprise where responsibility is assumed, and here as in all other such enterprises success or failure is dependent

on the organization and character of the men. A great advantage, aside from efficiency in teaching, of having professors in close touch with the outside world, is that such professors can place many of the graduates in positions for which they are especially fitted. This naturally can only be done where the professor, in addition to having a large acquaintance in the practical field, also comes into intimate contact with the students so as to know their individual peculiarities and characteristics.

Let us now consider the broad aspect of education. "We live to learn" applies most truly to the engineering profession. We must continue to study and learn as long as we hope to be active and advance in our profession. Just as soon as one reaches a point where he does not appreciate the value of other people's views, just so soon will he come to a standstill. It has been truly said that a big man will take most kindly to suggestions and that only the little man will resent them. We learn from day to day and soon appreciate the fact that time spent at school is but the beginning of a lifelong course. How does the school course assist us, and what should it include to be of most use? How long a course should it be, and should we send our sons to college? In the replies respecting the Carnegie qualifications, knowledge of the fundamentals of engineering science and technique of practice and of business were placed at the end of the list. If the judgment of those who responded is correct, are we not taking too much valuable time for such training, and would it not be just as well to shorten the college course? It is an open question whether much could not be eliminated from the college course to advantage, provided special attention is given to teaching the fundamentals. Once thoroughly mastered, the student will always carry with him the fundamentals of physics and mechanics, whereas much that relates to special applications will soon be forgotten. Again, the college should graduate its men young enough to preserve the adaptability of mind which the younger man possesses to a far greater degree than an older. If the assumption is made that the fundamentals are thoroughly mastered and the student graduated a year in advance of what he would be should he study along a number of specialized lines, most of those who employ graduates would favor the younger man with a keen knowledge of the fundamentals to the older man with what might be a lesser knowledge of the fundamentals and more knowledge of specialized lines. The question of whether the school course should be shortened depends on how it is shortened. Shortening the time spent in college may not shorten the course of study as a whole.

As far as can be determined from statistics, the average age of graduation from college has not changed appreciably during the past century, being somewhat over twenty-one and a half years. It would therefore seem that, irrespective of what is taught, there are elements entering a college course which have led to men graduating at about this age. I believe it advisable to have a four-year college course, but I would make the entrance requirements and the course such that the students would be graduated at as early an age as has been and is the current practice.

I have taken the stand and firmly believe that our present entrance requirements do not accurately gage the ability of an applicant, and that it is a mistake to make the entrance requirements too high for an engineering college. High technical requirements may result in the preparatory schools specializing along narrow lines in an endeavor to have the student enter college at an early age, to the sacrifice of a broader education. Again, high technical requirements discourage those who have worked in machine shops and the like and later on desire to enter a college. I have watched and encouraged such men and appreciate how hard it is for them to bring their minds back to the different studies; still, once these men get the right hold, they make the best of students and later the best of engineers. Where I have expressed this view the question has been asked, "How can we select men for the colleges if we do not rely on examinations, and how can we secure as good men with lower requirements as with higher requirements?" My reply has been that, in addition to the examinations, each and every applicant should be met by a board, and all of the circumstances connected with his case considered. Further, the examinations should be given in a way that will bring out the reasoning powers of the students, which can be accomplished if each man is given an oral examination of some length. Here again we have the harder against the easier way, but I am firmly of the opinion that there is no easy way of doing good teaching.

There can be no doubt that for many classes of engineering work much in the average college course is not needed. In certain instances we might well give over some of the time spent in specializing to teaching the fundamentals, with enough application to secure a thorough drill and to give the students confidence in their ability to solve practical problems. Fundamentals can be thoroughly mastered only through application. Further, it has been my experience that in training the average mind the fundamentals must be approached from different viewpoints, and that there is a great advantage in several teachers presenting subjects requiring the fundamentals to be applied in various ways. A student may memorize all definitions and be able to solve certain problems in a routine way, but on viewing a principle from another angle from the one to which he is accustomed he may be completely at sea.

The aim in teaching should be to produce a man who will be the most useful to his fellow-men and to his country. Just as we give, so we receive. The fruit of usefulness is achievement, and the building up of achievement, success. We should above all consider the human side and aim to produce a broad man with spirit and determination. It is my firm belief that in many cases we could produce graduates who would more nearly meet our ideals by cutting out much from the present courses of study and by teaching more thoroughly matter already in the courses. The course should be broad enough to include some of the so-called cultural studies, and it further should deal with the business side of the profession. Dr. Alexander C. Humphreys was the first to introduce a regular course of economics in an engineering college, the course including accounting, depreciation, shop cost, law of contracts, specifications, appraisals and business methods in general. As an illustration of matter already in the course that it would be well to teach more thoroughly, I can refer to the writing of concise and logical reports in good English. To this might be added speaking on one's feet before a meeting.

To really know a thing one must have more than an abstract knowledge. Much can be gained by having the students make or witness experiments which verify or illustrate the principles. What a student does with his hands in connection with his head he remembers far better than knowledge which he has obtained from text-books or lectures. The courses in departments having laboratories should be so arranged that work in the laboratories is given in parallel with the work in the class room. There must be close coöperation between the departments, with this end in view. It was a part of my pleasant duty when teaching to review the fundamentals after they had been taught by others. Good results came through the use of

apparatus to illustrate the principles and in giving the students practice in the solution of many problems in which the principles had to be viewed from different standpoints. That the apparatus helped was evidenced many times by the students sketching out the principles as applied to the experiments before they applied them to a problem, which showed that they carried the principles through a visual recollection of the experiments. Again, the principles were applied over and over again in laboratory experiments. To thoroughly master principles the hand, sight, and mind must be brought into intimate harmony and brought into harmony many times, and unless this is done the student will not have an understanding that will make the principles dependable working tools.

Instructions for laboratory practice are often so complete that the students are led to such an extent that there is a failure to call for the proper amount of initiative. This may or may not be so with a given set of instructions, all depending on the way in which the teacher presents the subject. He may often economize much time by using properly prepared notes, and he may train the initiative by inspiring the students to follow up the details and bearing of the experiments. Special exercises where the students are required to determine certain quantities without the use of any instructions, either oral or written, or with few instructions, form a most useful adjunct, but here again all depends on the way in which the subject is presented. Too much should not be done in setting up laboratory apparatus for the students. The men should be encouraged to ask questions; where questions are not asked it is a sign that something is wrong with the method or the teacher.

Laboratory exercises form a useful basis for practice in writing reports. The best results are secured by returning all reports with carefully marked criticisms, and requiring the student to rewrite those that do not come up to the standard. It may often require two or three or even more rewritings to make a report readable, but if this method is followed up conscientiously it will result in vast improvement. Here again the method is not the easiest one. A lack of proper examination of reports soon results in a falling off in interest and in the effort of the student. There is nothing more discouraging to a student than to have his work carelessly examined, and in good teaching much time must be spent on this part of the work.

As to education in general, we all agree that our sons should be trained along well-balanced courses. The shop foreman who received only a grammar-school education will send his son to college, for he knows what it means to be handicapped through lack of training, and how hard it is to make up for that lack of training by studying at nights later in life after long working days; as study he must to keep in the race with the college-trained man. In many instances where I have worked long enough with the men at a plant to really know them, it has been touching to find how many, especially the older ones, appreciate the fact that they have lost their opportunities. Many a time such men have come to me and said that I should make it my duty to warn young men to get an education. Yet many of these men had all the qualifications in the Carnegie list except the two items which those discussing the list have classed as the least important. One does not have to turn to the successful man to find character; many a man who has missed his chance has noble qualities and is a prince at heart. We should not therefore belittle these two items, even though we agree on the importance of those that precede them, for their lack has led many a man to failure.

One of the greatest pleasures of the professor is to watch the progress of those he knew so well after they leave him. It is indeed interesting to see the boy in the man, for although his students may grow old, there are still the same traits and peculiarities. The professor has a grave responsibility in that he directs while the mind and character are in a plastic state and his imprint may mark the destiny of his charge. It has been truly said that training a boy is like growing a young tree: easy to direct if taken in time, but hard if neglected or if started in the wrong way. Again, boys develop like growing trees: some young, sturdy trees may outtop the others, some may be checked for lack of space for development and transplanting to some congenial spot may help. It would be a poor planter who would discard some thrifty, young tree that might not come up to all his ideas of symmetry. The good planter would so bend and train it that its development would overcome its faults.

Having outlined the general principles of engineering education, the question may be asked, how should we proceed to obtain the best results? I believe that much good would be accomplished if those who employ graduates would coöperate in laying out the courses of study. The visiting boards of some colleges are a step in the right direction, but we need something closer and more concrete than is secured through most such boards. The engineering societies could do most fitting and useful work if they would go seriously into the problem. What is needed is a careful consensus of the judgment of many. A single man or a small group of men might have radical ideas which might do much harm if enforced. Even though an idea may be essentially good, care should be taken that the pendulum is not swung too far one way or the other, or the course will be unbalanced. All of us who have taught know of the frequent requests made by engineers, usually graduates of the colleges, that instruction be given along particular lines which have been of importance to them, and that should even a fraction of such requests be complied with the course would soon be overcrowded, or if other matters were dropped would soon consist entirely of specialized branches. The demand for instruction along particular lines has resulted in the courses of technical colleges being crowded at the expense of efficiency, and no additions should be made unless these seem desirable after a thorough study of the course as a whole to make sure the added matter will not displace something more valuable or result in a lesser degree of thoroughness in some more important branch.

We often hear the statement that something should be added to teach common sense. If by this is meant adding something to keep the student awake to the fact that there is much more for him to do than memorize and that he should keep his mind alert to grasp and coördinate facts and essentials, the suggestion is a good and basic one. The idea that there is a lack of common sense in graduates of colleges is sometimes overcarried. Often the one making the statement has a mind so fixed that he regards a graduate who does not look on a thing in the exact way he does as lacking in capacity. He wrongly regards the failure to follow fixed methods in reasoning as a lack of what he considers his own good common sense. The very failure to follow fixed methods is a safeguard which has been cast about the young mind to insure advancement and progress. Were the world to follow along the lines laid out by our older friend with his highly prided but set ideas, we might soon be in a rut that would prevent all advancement, whereas the young man, though he may fail, may also win through starting out enthusiastically in new and unknown fields. Let us therefore forgive the young man if he makes mistakes in matters that seem self-evident, and remember that the very freedom of his mind is the greatest safeguard for continued progress.

Summarizing, I would make the following suggestions:

1 That there be a closer cooperation between the engineering colleges and those employing graduates, and that the engineering societies be encouraged to work along this line.

2 That the technical requirements for entrance to colleges be lowered rather than raised, that preparatory schools be encouraged to give more attention to teaching good English and to giving a broad general education, and that applicants be also judged as to their initiative and general make up in deciding whether they should be admitted.

3 That the courses be so arranged as to train the initiative and develop the human side; that the students be taught to work in a cheerful and efficient way; that there be proper time for daily relaxation of the mind and that the students be encouraged to use this time to the best advantage.

4 That the professors get down to hard work with their students and know all of them well enough to be thoroughly acquainted with their personal characteristics.

5 That the professors in practical engineering subjects have practical experience so that they can speak with authority.

6 That professors in charge of practical engineering departments be encouraged to undertake practical engineering work, and that their college work be so arranged that they can be relieved from meeting classes when the engineering work makes this necessary.

7 That special attention be given to teaching the fundamentals of engineering science, even though this may result in the elimination of certain specialized branches.

8 That greater practice be given in the writing of concise and logical reports in good English, and in speaking on one's feet.

9 That the students be encouraged to confer with the professors, and that regular hours be provided for this purpose, all to the end that the teachers may extend a helping hand where needed and that there be a mutual understanding and trust.

TRIBUTE TO JOHN E. SWEET AT ANNUAL MEETING

As a tribute to the late Dr. John E. Sweet, Past-President, Honorary Member and a founder of the Society, who died on May 8, 1916, the regular business of the Annual Meeting was suspended at 12:30 p. m. on Wednesday, December 6, when a memorial service to Professor Sweet was held in the Auditorium of the Engineering Societies Building.

Prof. John H. Barr presided at the exercises, and the members of the Council and of the Council-elect, and the past-presidents of the Society took seats upon the platform. The Chairman announced that the ceremony would open with an address by Mr. Worcester R. Warner, Past-President of the Society, and Capt. R. W. Hunt escorted Mr. Warner to the platform. Mr. Warner paid the following tribute to the memory of Professor Sweet:

MR. WARNER'S TRIBUTE

In honoring the memory of Prof. John E. Sweet we stand at the shrine of one whom to know was to admire and love—of a personality instinct with qualities that live to bless the world endlessly, through perpetuation in the lives of others.

To all members of The American Society of Mechanical Engineers he was known as the revered founder and third president of this Society.

As long ago as 1880 I, myself, received a letter from him in which he outlined the scope and benefits of such an organization and invited me to become a charter member.

In those remote days the term Mechanical Engineer had a very limited application. It did not appear in college courses or degrees. There were some Master Mechanics and Master Builders and Draughtsmen; but to secure sufficient members as a nucleus for his proposed organization, Professor Sweet had to invade the ranks of Foremen and Machinists—and there, I may add, is where he found me and some others.

Recently he wrote: "Likely the most important thing I have done was to set the ball rolling for the organization of The American Society of Mechanical Engineers, of which there are between four and five thousand members scattered throughout the inhabited surface of the world." As he was proud of the founding, justly so may we be proud of the founder.

Professor Sweet left a brief and very characteristically modest outline of his life history from which it appears that he was born, of plain English parentage, in the village of Pompey, near Syracuse. His educational advantages were few but he and a brother developed marked taste and aptitude for mechanics. "I was always at making something," he says. Not unnaturally, therefore, he eventually learned the carpenter's trade, from which, as he says, his "mechanical life ran into architecture," and he adds that there are in Syracuse several buildings designed by him. Whimsically he explains that as "the Government at the seat of war at that time was giving jobs to those who wanted to stand up and be shot at, which was a job he 'didn't hanker for,'" so, in 1862, he went abroad and "visited London, Paris, Switzerland and Italy." For nearly two years thereafter he had employment in England. On his return to America he invented his very ingenious but commercially impracticable machine to supersede movable type—the forerunner of the linotype. Then he undertook bridge construction and tells how it was while he was building a bridge at Ithaca that "President White and Mr. Cornell came around one afternoon" and asked him "to meet the Cornell Board," from which resulted his appointment as Director of Shops in Sibley College. The six years, from 1873 to 1879, during which he taught there, were full to overflowing of activity in the interest of his "boys," between whom and himself existed those remarkable bonds of regard and affection expressed in their long series of annual gatherings with him in recent years. "At Cornell," he says, "we were constantly developing new things: absolutely perfect surface plates, straight-edges, squares and angles, standard gages — by the use of the measuring machine which we built (the first ever built in this country) and which read to the ten-thousandth of an inch and enabled us to judge the forty-thousandth. Visitors to the University were always shown our shop and the wonders of the work we were doing interested the greatest of them all. Mr. Cornell was a constant, interested visitor while he lived. General Grant, John Hay and hundreds of others came." "In conversation with Henry Ward Beecher," he adds, "I casually remarked that an ordinary college graduate was not much use in a machine shop and he said he guessed I had never seen one in a pulpit!" Another incident that diverted the young professor, he thus describes: "We built certain

lathes, and, among other new things, all the bolts and nuts that had to be changed to meet conditions were made to be operated by the one wrench. Showing it off to a friend, he said, 'What in the world would you do if you lost that wrench?'" With deep feeling he sums up that period thus: "The best thing we made or helped make at Sibley, I suppose—or hope at least—was a lot of valuable men." From these fine men, "Sweet's Boys," have proceeded such answering testimony to the worth of their instruction by this tireless, inspiring teacher as constitutes, it seems to me, his most perfect tribute and imperishable monument.

One of them, Dean Smith, of Sibley College, writes me: "My memory pictures Professor Sweet always at work upon something that should contribute to the training of the students in his charge; and no matter how busy he was, he was always ready to give his attention to any one who sought his instruction or advice upon any matter whatever." "One thing he said has always stuck in my memory," adds Professor Smith. "It is so characteristic of the man. He said: 'When you go out into practice you will not be paid for what you know but for what you can do.'"

Another of these former students, Mr. J. E. Johnson, Jr., has written a masterly appreciation of Professor Sweet which will shortly appear in *The American Machinist*. To it I am indebted for certain details and the extracts from Professor Sweet's reminiscences. Much stress is laid by his students on Professor Sweet's ingenious applications of graphics to replace the higher mathematics of his subject. Mr. Johnson mentions this interesting instance: On one occasion during a call from some professor the latter spoke of the very difficult problem in geometry which the mathematicians had just succeeded in solving, namely, that if three circles of different diameters are drawn in any position in a plane and a pair of tangents are drawn to each side of each pair of circles and prolonged to their intersection, the intersecting points of the three pairs of tangents will lie in a straight line. Professor Sweet thought this over for a few minutes and said: "Yes, certainly, I can see that that is true." The other professor said: "I guess you don't understand, Professor. This is a very difficult problem and we have just finally accomplished its solution. I don't think it is as obvious as you think it is." "Why, yes," said Professor Sweet, "of course it is obvious. Instead of three circles in a plane, take three balls lying on a surface plate. Instead of drawing tangents, imagine a cone wrapped around each pair of balls. On top of the three balls lay another surface plate. It will rest on the three balls and will necessarily be tangent to each of the three cones. The apexes of all the cones must lie in the intersection of two surface plates, and as the intersection of two planes is always a straight line, the apexes of the cones will lie in a straight line. It seems to me that this is perfectly obvious." So it was to a man who could think in those terms, but to how many of us, no matter what our mathematical training, would it be "obvious"?

At the Centennial Exposition in 1876, the notable feature of the Sibley College exhibit was Professor Sweet's Straight Line Engine, constructed at the college shop. As a marked departure in design from previous types, it attracted much attention; the more so since, when tested out, it developed a high efficiency. Encouraged by these facts, the inventor decided to leave the teaching profession and to devote himself to the manufacture of his engine in his home city of Syracuse. So the Straight Line Engine Co. was organized in 1879, with Professor Sweet as President—an office he held until his lamented death—and there Sibley College post-graduates and others of "Sweet's Boys" received their advanced practical training.

Many present, beside myself, must remember the kindly sentiment, "Visitors Always Welcome," cut in the stone over the entrance door of the factory, and, like myself, must have put it to the test more than once, only to find that welcome ever ready. And the straight-line engine itself was a familiar friend, too. We installed one in our first shop, Swasey and I, and used it until we needed more power. Then it passed to Brashear, in whose shop it is working steadily still—a tribute to the inventor's sound sense and feeling for right design.

Professor Sweet's name and fame became so well known that engineers and inventors made "a beaten path to his door."

It was his pleasure to commend and aid those who possessed merit. Just as ready was he to wisely direct those who came bringing heretical ideas in opposition to the fixed laws of mechanics. In such cases his keen sense of humor often played a kindly but convincing part. On one such occasion an inventor, after demonstrating an elaborate model, asked, "Now, Professor Sweet, what do you think of it?" Instantly came the characteristic reply, "Well, it seems to be a mighty good way to do a thing that doesn't need to be done." I recall, in the days when inventors tried to apply ball bearings to everything from bicycles to the axis of the earth, one such went to him to explain the merits of his new ball bearing for buggy axles. Professor Sweet listened attentively and then said to the proud inventor: "The ordinary buggy axle is of steel, about 7/8 in. diameter, nicely fitted to a cast iron sleeve and, presumably, well oiled. If you place such a buggy on a new, smooth floor, and with a sensitive spring scale, determine how slight is the power required to move it, you will see that, if your ball bearing saved it all, it wouldn't be worth while." He followed this statement by saying, "The resistance to moving vehicles is mostly on the ground and can be best overcome by making better roads." This now seems like prophecy, in view of the fact that the State of New York has, since then, spent over one hundred millions of dollars in improving its roads.

Thousands of young mechanical engineers discover the great loss of power by the use of the crank in the steam engine and are then subject to attacks of the rotary-engine fever. Most of my hearers have doubtless prescribed for this malady and accomplished cures. So did Professor Sweet. For, when one thus afflicted came to him with a splendidly worked out design, the cylinder but half the usual circle, and enthusiastically invited his approval, Professor Sweet said cordially, "It is the very best rotary engine I have ever seen, for you have at the outset, thrown away half of it. Now all you have to do is to throw away the other half." Then we may be sure he gently put that young enthusiast back on the right track to real progress. This characteristic helpfulness to others held good to the very day of his death. For another of his "boys," Mr. Wm. C. Brown, tells me that on the morning of that day—it was the eighth of last May—a man from Texas, whom he had never heard of before, walked into the Professor's office to ask advice about a valve motion he had invented. When it had been explained but before Professor Sweet had an opportunity to express an opinion, his carriage came and he was obliged to go home to lunch, making an appointment for the man to return at a later hour. That afternoon the fatal stroke occurred and Professor Sweet was taken home by Mr. Brown, in the latter's car. On the way, though suffering intense pain, he told Mr. Brown about the stranger's errand and begged him to see the man when he returned and explain to him just why his valve motion was of no value.

Here is the great human note, without which even the harmonies of Heaven would be poor.

In these latter years Professor Sweet had enjoyed much travel. Of this he writes: "I have crossed the Atlantic fifteen times, have been in ten seas, twenty two countries, and in too many rivers, bays and cities to enumerate. I have been four hundred miles South of the Equator and half way to the North Pole." So he took a warm interest in world politics, especially as affected by the present war of nations. This is the theme of several personal letters written to one of his very favorite "boys," Mr. F. G. Tallman. Recalling Professor Sweet's sentiments concerning the Civil War we are prepared to find him saying: "I have said, and said it years ago, that 'Prepare for war in times of peace' is the worst sentiment in the English language, and if anything was necessary to prove it, the present war does it. Men fight more for glory than anything else and there would be no glory in taking an unprotected country but a disgrace to the people who would do it. I believe this country would be in a safer condition without a cent's worth of arms, armaments and forts than with the best possible of those elements." These are vigorous words from a man of 82. Several letters are in the same vein. All express, at more or less length, his utter detestation of war and the specious excuses other men make for it.

As I turn the pages of this very private correspondence, kindly sent me by Mr. Tallman, I find one letter in quite another and a very amusing vein. I quote: "Some two weeks ago I got thinking about what was the first thing I ever made that I could remember about—and it was a boot-jack that I made somewhere about 1840, or when I was eight years old. And I called to mind the fact that I did then what I have always tried to do since—make it better than the ones made before." Then the writer tells how, being up at Pompey a few days before and mentioning the boot-jack, some one "went out in the wood-house and brought it in" and, he continues, "I have it now in my office. Wherein it differs from others is this: the old, or, in fact, all others, have a cleat under near one end, to hold that end up. In the place of the cleat, I have two holes through and put in two pins which I let project out from each side, so the jack is right side up whichever is put on the floor. As an evidence that it was used in the days of boots, the back end is worn tapering and the forked end has been worn by the boot heels. The point is that I did then what I have always tried to do since—*make the thing better*. But getting other people to adopt my notions has been as barren of results as my notions about preparedness."

Likewise, in his reminiscences, Professor Sweet writes: "I cannot call to mind ever starting on a job without thinking out how to make it better than it had been done before." The engineers of the world can set themselves no higher task than such a motto imposes, nor hope to accomplish it more fully and nobly than did Professor Sweet that which he undertook.

Simple and modest and self-effacing as he was by nature, honors sought him—not he them. In 1914 the John Fritz medal was awarded to him "for his achievements in machine design and for his pioneer work in applying sound engineering principles to the construction and development of the high-speed steam engine." In the same year Syracuse University conferred upon him the honorary degree of Doctor of Engineering. But, as has been truly said, these honors, great as they are, are less lasting than will be "his influence over men, to cause them to think straight and live honorably."

The man of whom such things are true need make no claim of his own. In life he is revered. In death, we bring him the homage of our hearts.

The Chairman expressed the Society's indebtedness to Mr. Warner for this appreciative estimate of Professor Sweet. He then introduced another pioneer of the Society who was associated with Professor Sweet in his early days, Capt. R. W. Hunt. Captain Hunt said in part:

CAPTAIN HUNT'S TRIBUTE

"Blessed are those whose works are such that every day and every moment of that life has been to make their fellow men better and happier, and such was Professor Sweet. His life was as simple as his mechanical ideas, and just as accurate in its greatness and in its purity. To know him was to be blessed, and certainly his influence exerted upon those who came in contact with him, and left as a beneficence to those who follow him, is of a character that makes the world worth living in.

"His achievements were not of a startling kind. His successes did not bring to him great fortune, but each one made men better and happier, and the fact that following the years of his teaching he established a brotherhood of love among men who continued to pay tribute to him until the day of his death was an achievement of which any man should be glad and proud, and sufficient to content any man."

The Chairman then called upon Prof. Albert W. Smith, Dean of Sibley College, Cornell University, who was one of the Sweet boys in the early days of Cornell, and was afterward superintendent of the Straight Line Engine Works.

DEAN SMITH'S TRIBUTE

Professor Smith said he counted it one of the pleasures and privileges of his life that Professor Sweet was his teacher in Sibley College and his employer in the Straight Line Engine Works, and that there were two things which characterized his knowledge of Professor Sweet: *first,* his clearness of thought, and, *second,* his deep human sympathy. Dean Smith continued:

"As I said once before in public, Professor Sweet all of his life carried a little sharp needle to prick hot-air balloons, and then when he saw the balloon collapsing, his sympathy for the man who had brought it to him was so great that he would explain to him a way to blow balloons so that they could not be punctured.

"I want to tell one story that has not been told here this morning. The Professor was especially proud of the Straight Line engine because, although it was a high-speed engine, it ran silently. One day, a man from Syracuse came to the works, and a Straight Line engine was on the skids ready to be shipped. This man was not an engineer. He came in and the Professor greeted him, and he said to the Professor, looking at this engine, 'I see you are still making drop hammers.'

"It seems to me that in human life there is only one cardinal sin, and that is selfishness. All others are simply outgrowths or modifications of this one sin. It is the one of which Professor Sweet was guiltless all his life, for he was the kindest and most unselfish man that ever offered help and sympathy to harrassed human mortals. I am proud of the fact that it was given to me to be one of Sweet's Boys."

The Chairman in conclusion said that it seemed proper to those who knew Professor Sweet and loved him so dearly that this memorial should be characterized by extreme simplicity and brevity, and with these tributes the service closed.

MISCELLANEOUS SESSION, WEDNESDAY MORNING

At the first Miscellaneous Session of the Annual Meeting, at which Dr. D. S. Jacobus presided, the following five papers, contributed by local Sections of the Society during 1916 and published in The Journal, were read by title:

Steam Safety Valves, George H. Clark, contributed by the Boston Section.

Efficiency of Propulsive Machinery and Late Developments in Naval Engineering, H. C. Dinger, contributed by the Philadelphia Section.

Standardization of Power Plant Operating Costs, Walter N. Polakov, contributed by the New York Section.

Report of Efficiency Tests of a 30,000-kw. Cross-Compound Steam Turbine, H. G. Stott and W. S. Finlay, Jr., contributed by the New York Section.

The Design and Test of a Large Reclamation Pumping Plant, G. C. Noble, contributed by the San Francisco Section.

MR. ORROK GIVES FORMULÆ FOR THE PROPORTIONING OF SURFACE CONDENSERS

George A. Orrok then presented a paper entitled The Proportioning of Surface Condensers, in which he enunciated the following principles:

a The law of temperature rise in a condenser tube is of the exponential form, with 0.875 (0.9 or 0.8, perhaps) as the exponent

b It is not necessary to take viscosity into consideration in designing where the water temperature is 65 to 70 deg. fahr. and the vacuum is 28 in. or over

c Critical velocity may likewise be neglected, since all condenser velocities are far above it

d For velocities obtaining in condenser practice the coefficient K may be taken as the 0.6 power of the velocity

e The reduction in heat transmissive power due to the presence of air in a condenser is very approximately covered by the use of a term $(P_s \div P_t)^2$ as a reducing factor of K

f For design work the value of K may be reduced once for all to account for the cleanliness of the tube and the material itself

g The value of K will then be reduced to somewhere between 300 and 400 for design purposes, say 325 for average good working.

Mr. Orrok presented the following formulæ covering the application of the results of his experiments to the design of surface condensing apparatus:

If P_v = absolute pressure in condenser = 29.92 — (vacuum — 0.2 in.)

t_s = temperature of steam corresponding to vacuum

t_0 = initial temperature of condensing water

t_1 = final temperature of condensing water = t_s — 5° for close work, ordinarily = t_s — (7° to 10°)

λ = total heat of steam at t_s

q = heat of the liquid at t_s

Then, ratio of condensing water to steam condensed is

$$R = \frac{\lambda - q}{t_1 - t_0}$$

Also, pounds of steam condensed per hour = W, and weight of condensing water used = $Q = WR$.

One-inch tubes (No. 18 B. W. G.) being taken as standard on account of advantages generally conceded to that size, the number required in one pass = $n = Q \div 990 V_w$, where V_w is the velocity of flow, averaging 8 ft. per sec. (7 to 10 ft.).

The length of water travel (l), or the total tube length, may be found from

$$l = \frac{30.8\,Q}{325\,V_w^{0.6}\,n}\left[(t_s - t_0)^{0.125} - (t_s - t_1)^{0.125}\right]$$

and the total tube surface (S) from $S = 0.262\,nl$.

The cross-sectional area of the condenser (sq. ft.) is equal to ($n \times$ number of passes) $\div$ 60, where 60 is the average number of tubes occupying 1 sq. ft. of tube-plate area. The length of the condenser = $L = (l/m)$ + depth of water boxes, where m = number of passes.

The author said, in presenting his paper, that the data in it were ten months old, but that he had heard of no experiments since which would cause him to change anything in the paper. He said that at the present time we unfortunately lack experiments to confirm our conclusions regarding the air question, and there might one or two things come up within the next few months to cause him to change his opinions. If so he would come back later and say that his paper was no longer correct.

William Kent, in opening the discussion, said he had no fault whatever to find with this paper, except that it needed an appendix, and he hoped Mr. Orrok would next year give another paper supplementing this one.

The principal question he wanted answered was: Given, say, a 1000-hp. engine, with 10 lb. of steam per horsepower, which would make 10,000 lb. of steam, and with 29.5 in. of vacuum and 70 deg. fahr. temperature of circulating water, how many square feet should be put in the condenser, and how should the square feet be arranged? The temperature of the condensing water, the vacuum, and the number of pounds of steam to be condensed are the only things we have to begin with, and the two things to be found are the number of square feet and the arrangement of the heating surface.

Wm. D. Ennis thought that if the author would explain the statement: "The law of temperature rise in a condenser tube is of the exponential form, with 0.875 (0.9 or 0.8, perhaps) as the exponent," the surface capacity could be readily determined.

Thomas C. McBride said that a number of condensers had been built in which the circulating water was heated in the neighborhood, taking an actual instance, of from 70 to 95 deg., but now we find it desirable to force a lot more water through and lower the average water temperature and thereby increase the total amount of heat transmitted per square foot. That brings up the question of the length of tube possible with the increased amount of water, as it influences the horsepower of the circulating pump.

He put up on the blackboard his own equation for determining surface, which checked up because with it the amount of surface multiplied by the length traveled through by the water was constant.

Geo. H. Gibson and Paul A. Bancel wrote that they thought that the author has given more attention to the devising of algebraical formulæ than to explaining the fact, which is clearly patent, that single-tube experiments and practical condenser results are 100 per cent or more apart.

Values of the coefficient K varying from 470 to 630 are mentioned as experimental results. Upon proceeding to put down principles which can be used in designing, however, the author says "The value of K will then be reduced to somewhere between 300 and 400 for design purposes, say 325 for average good working." As a matter of fact, coefficients equivalent to 300 have been attained for years in old-fashioned condensers without the grace of new-fangled formulae and with tubes packed 100 or more to the square foot and only 3 or 4 ft. per second water velocity, whereas the author recommends about 69 tubes to the square foot and 8 ft. per second water velocity. If all the new formulae get us no farther than this, why formulate?

The conclusion is unescapable that what takes place in an individual tube surrounded by pure steam is, in the actual condenser, submerged and obscured by some other factor or factors. Has sufficient study been given to the flow conditions on the steam side of the tube?

Just as there is a best tube length for the water flow, so there is a best tube-bank depth for the steam flow. As condensers grow in size, it is not correct merely to make them deeper in proportion as they are made wider. The best depth must be determined and increased capacity obtained by spreading out in the other dimensions. Steam lanes in the tube bank do not solve the problem, for they are like by-passing water directly from the cold-water box to the warm-water box; some of the heat-transmitting surface is by-passed by the lanes and becomes stagnant and inactive because of accumulation of air. Another solution which has been proposed, viz., to keep every tube in the condenser bathed in pure steam summer and winter, heavy loads and light loads, by pulling a larger proportion of the steam through into the air pump, leads to an excessive power consumption by the latter.

Mr Bancel supplemented the above discussion by considering the effect of size of condenser on efficiency. He said that condensers are getting bigger and bigger nowadays, and it has been assumed that the condenser would be more efficient in large sizes. One reason for this was that the turbine is more efficient in large sizes, but the problems that come into condenser design are very different from those that enter into the case of the turbine.

M. C. Stuart presented a comprehensive written discussion in which he gave the results of his own analysis of the author's data. Some of Mr. Stuart's conclusions were:

"Undoubtedly the data presented show conclusively that the heat-transfer factor did vary as a function of the mean temperature difference between steam and water. The runs used to reach this conclusion, however, included only those in which the steam temperature was constant and the inlet-water temperature varied. A set of runs may sho wthat the heat-transfer factor varies with the temperature difference, but this does not mean necessarily that the variation is *because* of the temperature difference. At constant steam temperature, small temperature differences correspond to high actual water temperatures, and it is altogether possible that the variation obtained by Mr. Orrok was due to the variation in actual water temperature, rather than to the variation in temperature difference.

"I agree that for the narrow ranges of temperature existing in condenser work (from 70 to 90 deg.) the effect of viscosity need not be considered. It would also appear that the effect of varying temperature differences need not be considered, especially in view of the evidence that the heat-transfer factor varies with actual water temperature and not with temperature differences.

"As to the relation of heat-transfer factor and velocity, I find that the plot of velocity *vs.* heat-transfer factor on log paper gives a line which is decidedly curved, and which indicates an exponent varying from 0.5 to 0.6 in the formula $U = CV^n$ over the velocity range from 2 to 8 ft. per sec."

"The author chose 8 ft. per sec. velocity only because this is usual. At a velocity of 8 ft. per sec. the friction drop amounts to 10.73 ft. of water and the total length of tubing amounts to 3250 ft. per million pounds of water per hour. By increasing the velocity to 12 ft. per sec. the total length of tubing may be reduced to 2570 ft. at the expense of an increase in the friction drop to 25.24 ft. of water. The writer is not advocating the use of any particular velocity, but simply placing emphasis upon the fact that the proper choice of a velocity should be given more consideration."

G. L. Kothny, in a written discussion, stated it would be interesting to hear what amount of air leakage in pounds per hour should be assumed per 100 sq. ft. of surface when using 325 as the value of K. He thought an attempt should be made by condenser manufacturers to agree on the maximum and minimum amount of air leakage permissible for certain sizes of condensers, and that the establishment of such standard figures would give a better basis for comparison of the efficiency of different types of condensers. It would be interesting to hear from Mr. Orrok if he has any data referring to the maximum and minimum amounts of air leakage in pounds per hour for different sizes of surface condensers, such as 5000, 10,000, 25,000 and 50,000 sq. ft. cooling surface.

He suggested that, to avoid misunderstandings, the symbols used for making condenser calculations should be agreed upon or determined by a standard committee of members of the Society engaged in condenser work.

Alphonse A. Adler entered into a lively discussion of the formula given by Mr. McBride, criticizing it on the score that it was physically inconsistent. Professor Kent and Mr. McBride joined in and the discussion became a question of meaning of a dimensional formula.

The author said in reply to the query of Professor Ennis regarding the exponent $\frac{7}{8}$, that in the closure to the discussion of his paper before the Society three years ago he showed three dimensional diagrams which would make clear what he meant.

What we would like to know about a condenser is whether, plotting the temperature rise of the water against the length of the tube, the arithmetical rise is true, the logarithmic rise is true, or the exponential rise is true. On that depends the whole mathematics of the thing. The reason this is non-dimensional, as Professor Adler says, is because it works on the arithmetical mean. You can have a thousand tubes one foot long, or one tube a thousand feet long, and get the same result in the condenser.

He thought Mr. Gibson had mistaken K for U. K is the coefficient, while U is the heat transfer, and that makes a big difference. The heat transfer is two, three or four times what the coefficient is. We get heat transference in a single tube up to 1200 to 1400, and in the condenser up to 700, 800 or 900, but the coefficient is rarely much over 400. The reason why we cannot get the high coefficient at low load on the condenser is that we do not have the heat to transmit. We have a large temperature difference, and therefore the value of U to the coefficient is very small always owing to that.

As to the depth of the tube bank, he said he would like to go into the question of the velocity of steam amongst the tubes, but it was a long subject and was covered pretty well in his original paper.

Regarding the criticism as to the velocity of water he took

in the tubes, he said he had assumed the customary velocity. The actual velocity to choose is a commercial question, depending on how much you are willing to spend for pumping power.

PROF. BRECKENRIDGE AND MR. PRENTICE PRESENT PAPER ON TESTING HOUSE-HEATING BOILERS

The second paper presented at this session was by L. P. Breckenridge and D. B. Prentice, on The Testing of House-Heating Boilers. In this paper the authors proposed a standard method for testing this class of boiler, a type of apparatus which has not yet received the attention of the Power Test Committee of the Society. The paper was presented by Mr. Prentice.

James W. Nelson made a motion that this paper be referred to the Power Test Committee of the Society for consideration for incorporation in the Rules for Conducting Performance Tests of Power Plant Apparatus, which was seconded and carried.

Geo. H. Barrus, C. M. Garland, Roy E. Lynd, C. B. Thompson, Max Friedlander, Allen Hubbard and William Kent contributed written discussions to this paper, the salient points of which follow:

Geo. H. Barrus, as a member of the Power Test Committee, thought it might be taken for granted that the Committee would welcome any suggestions for amendment to the Power Test Report such as the authors brought forward. He hoped, furthermore, that this paper would lead other engineers to study these codes with a view to pointing out any possible deficiencies.

C. M. Garland stated that this type of boiler and furnace has been notoriously uneconomical in the appropriation of the heat liberated by the fuel, and it is largely due to Prof. Breckenridge's initiative along these lines that the inefficiencies of these boilers have been brought to the attention of the manufacturers, engineers, and to the government experiment station. The result is that manufacturers have given the matter of efficiency serious thought, and house-heating boilers of excellent efficiency are now built.

The testing of this boiler is radically different from the testing of the high-pressure boiler as used for power and larger heating work. It is therefore desirable that a different code should be provided for the testing of these boilers. The one proposed by the authors would seem to meet the requirements of the different conditions. A heat-value unit for a standard measure for one foot of radiation would be a most desirable standard.

Roy L. Lynd was satisfied that tests made by competent engineers in accordance with the code outlined would be about as complete and accurate as it is possible to get them.

He thought it would be well to eliminate the term House-Heating Boilers from the code, and substitute Low-Pressure Heating Boilers.

As the proposed testing code is essentially a code for evaporative tests, we are not concerned with boilers for hot-water heating and hot-water supply. The new code should therefore cover all boilers used exclusively for steam heating and should be so entitled. The A.S.M.E. Boiler Code in Section 2 does not limit low-pressure heating boilers to 2000 ft. or less, and we should not so restrict the testing code.

He criticized the authors' definition of a foot of radiation, and suggested that a better arbitrary value than 242.6 B.t.u. per hour would be 250 B.t.u. per hour.

C. B. Thompson wrote that, if he had read the paper understandingly, its argument was that boilers are overrated because there has been no well-established or standard testing code, and hence errors in tests have led to errors in computing working capacities. With this he could not agree, as the code presented is only one of many by which boilers may be tested that will show practically the same results. It is when the tests are computed to determine the boiler's capacity in terms of square feet of radiation that guesswork is employed. The computer can give the capacity at which the boiler will operate for any unit of time if he knows the full capacity. Without this all-important item he is adrift in a fog.

If the capacity of house-heating boilers were computed something like the following, there would be less complaint of overrated boilers, because many buyers do not understand that the rated capacity is at the boiler outlet:

	Sq. Ft.
Capacity Cast-Iron Radiation	800
Add for Covered Pipe	150
Total Boiler Load	950
Coal will last, hours	9

Then give the chimney size required and the purchaser can select what he wants without outside assistance.

Max Friedlander, in his written discussion, contributed a new method for a *continuous* determination of the heat balance of house-heating boilers, which, so far as he knew, had not yet been published elsewhere. A description of this method will be given in a later issue of The Journal.

Allen Hubbard considered, in his written discussion, that if the manufacturers would rate their boilers on the basis outlined by the authors, the public and the business generally would be greatly benefited.

William Kent thought that the method of rating proposed seemed to leave out a most important factor—the grate surface, or the amount of coal that should be burned per square foot of grate surface.

Mr. Kent also proposed the figure of 250 B.t.u. for the square foot of radiation, instead of 242.6. This figure has long been used by heating and ventilating engineers as a standard equivalent for an average square foot of radiation.

The author promised to reply to the discussion in a written closure, which will be published later.

WATER PURIFICATION VS. BOILER COMPOUNDS DISCUSSED IN PAPER BY MESSRS. SCOTT AND BAILEY

The third paper presented at this session was that by Arthur C. Scott and J. R. Bailey, on Water for Steam Boilers—Its Significance and Treatment. The point in this paper was that the use of *boiler compounds*, except in plants of relatively small size, is less efficient and more expensive in preventing trouble than methods employed for the water purification before it enters the boiler.

William Kent objected to one statement in the paper, that the waste of fuel in a boiler caused by scale is proportional to the thickness of the scale, and claimed that the author's figures illustrating this were fifty years old and, moreover, rested on no authority whatever. He stated that the loss in heat due to scale on the tubes may be absolutely insignificant.

He commended what the authors said in condemning boiler compounds, but thought this statement might have been made even stronger.

W. T. Alliger[1] commented on the statement: "As a matter of fact, purification of water is partially obtained in most

[1] Harrison Safety Boiler Works, 17th St. & Allegheny Ave., Philadelphia, Pa.

cases by heating it to the approximate boiling point, but the hot process assumes that with steam enough to give a temperature of 200 deg. fahr. or over, sufficient soda ash is added to the feed water to just satisfy the alkaline earth sulphates and chlorides and any acid present, and the water is then satisfactorily purified." That might have been true several years ago when the practice was low temperatures with very little overload. But with the present development in boiler practice, where we carry very high overloads and high steam pressures, the statement is not correct. With the present practice, we require water as good as can be obtained, consistent with the amount of money we can spend in getting the results. In the most efficient plants they have even gone so far as to evaporate the make-up water, but in ninety-nine plants out of one hundred that is not permissible for economic reasons.

With a hot-process system you can get better results in purification than by any other means. In many cases he had seen results where the scale-forming impurities have been reduced to as low as one grain, in one case to half a grain, and in some others to about three-quarters of a grain. These results are controlled by the temperature. If you can operate your hot-process water softener under slight back pressure, say up to 5 lb., the results will be improved.

The authors take up the question of foaming, but there is probably as little known about the causes of foaming, as little proved on the causes of foaming, as anything connected with the operation of boilers. Personally, he was inclined to believe that the collection of suspended matter at the surface of the water has a greater influence on foaming tendencies than the constant breakings of the soluble salts, provided they are kept within reasonable limitations.

Written discussions of this paper were presented by Geo. H. Gibson, M. F. Newman and F. F. Vater, respectively.

Mr. Gibson considered that present water-softening practice was well summarized by this paper, except that the authors did not appear to be familiar with the latest development in hot-process softeners, which have made a radical advance, due to recent improvements in chemical feeding devices. Milk of lime is now fed as easily and as accurately as soda or caustic soda, or trisodium phosphate could be fed before. That chemical or combination of chemicals which will give the desired results at the least cost, all operating conditions being taken into consideration, can therefore be used in all instances.

Chemical reactions are much more rapid and complete in hot water than in cold water, as any one can satisfy himself by taking a sample of water, dividing it into two parts, heating one sample to the boiling point while leaving the other cold, and then adding to each the exact amounts of softening reagents theoretically required for the transformation of the scale-forming substance. There will immediately appear in the hot water a coarse, granular precipitate, which soon settles to the bottom. With most natural waters, no effect at all will be apparent in the cold water for ten or fifteen minutes, and even then only a slight haze. In due time a very fine precipitate will begin to come down, the sedimentation becoming complete, however, only after four to six hours. Even then, if the cold sample be heated to boiling, further precipitation will occur. This action is frequently observed where water from cold-process systems is passed through feedwater heaters.

In the hot water, complete reaction is also obtained with a smaller excess of reagent than in cold water, and overdosing is not necessary in order to reduce the total solids closely to the limit imposed by the solubility of the end-products, that is, of the substances into which the scale-forming matter is transformed by the chemicals. In fact, the manufacturers of hot-process softeners regularly guarantee to reduce scale-forming solids in solution to less than 2½ grains per gallon, and in actual practice the total solids in the treated water are frequently reduced to below 1 grain per gallon, sometimes to less than ½ grain per gallon.

The discussor here described an apparatus by means of which the softening reagents are fed with great accuracy and sensitiveness and which has been developed from his suggestions by the Harrison Safety Boiler Works, of Philadelphia. The description will be published later.

F. F. Vater's discussion was a defense of the hot process of water softening, which, he said, offers possibilities not obtainable by the cold process. He objected to the author's classifying this process with such devices as live-steam purifiers and boiler compounds, on the ground that the cold process would be more appropriately classified with these.

M. F. Newman, on the contrary, claimed that the most highly efficient water purification is carried on without dependence upon heat. The main factors in boiler purification, he wrote, are not heat, soda ash and blowing, with possible filtration, but accurate softening and purification carried out independently of the variables encountered in the irregular flow of water through the heater and the uncertain degree of precipitation within the heater. The authors attributed foaming and priming chiefly to a concentration of alkali salts, giving secondary consideration to silt, organic matter, loosened scale, lubricating oil, etc. It had been found, however, that in the absence of substances in solution which form precipitates upon concentration, water containing alkali salts could be highly concentrated without any appreciable effect on the steaming quality of the water.

This writer also discussed in a comprehensive manner a number of other points in the paper, and his discussion will be published in extended form later.

The discussion of Messrs. Scott and Bailey's paper was continued at the Miscellaneous Session on Friday morning, when Geo. L. Fowler discussed the paper orally.

Mr. Fowler said that it seemed to him that all of the formulæ given by the authors were such as could be found in any book on water softening. Ordinary ingredients like carbonate of iron and magnesium and sulphate of lime and magnesium we have known how to treat ever since Clark published his famous work almost a century ago. It seemed strange to him that one of the authors should have skipped over the ingredient which occurs in almost all boiler water—organic matter—which, in his opinion caused more trouble in such waters than anything else. He instanced the case of a certain railroad in which the metal in some boilers corroded very rapidly under conditions apparently the same under which other boilers did not corrode at all. It was naturally suggested that the fault was with the metal. In some cases this was found to be so, but in others, upon analysis of the boiler water, the latter was found to be no more like the feedwater than black is like white. Something resembling an alkaline solution was found to be in the water.

Building a small boiler and evaporating the analyzed water in it revealed the fact that the trouble was with organic matter in the water, which decomposed under high steam pressure.

Mr. Fowler thought that every case of boiler feedwater needed special attention. An analysis of the raw water could not be trusted to, and the only thing to do was to see what was going to happen to the water when it was evaporated under the same conditions to which it would be subjected in the boiler.

INDUSTRIAL SAFETY SESSION, WEDNESDAY MORNING

At this Session of the Annual Meeting there was presented for consideration a Proposed Code of Safety Standards for Cranes, which had been prepared by committees selected from a large number of representatives of important industrial interests and of insurance companies, inspection bureaus, etc., under the direction of the Industrial Commissioner of Pennsylvania. The Code in question is intended primarily for electric traveling cranes, but its provisions are designed to cover jib, monorail and hand-power cranes insofar as the various sections apply. The first half of the Code deals with details of design and construction, and the remainder with rules for crane operators, floormen, and repairmen.

In opening the Session, Chairman John H. Barr announced that the policy of the Sub-Committee on the Protection of Industrial Workers, under whose auspices the Session was held, was to confine itself strictly to the preparation of codes for safeguarding machinery, leaving propaganda work on the safety movement to other instrumentalities. The Code presented was to be considered a basis upon which should be finally developed a Code that would be adequate, make all necessary provisions for safety, and at the same time not be so drastic as to be beyond reason. The hope of the Committee was to formulate Codes that would be adopted and approved by state governments, resulting in uniformity of legislation. With the latter obtained, manufacturers would be quick to build in the safeguards which are now left to the user to provide.

At the request and in the place of Dr. John Price Jackson, who was unavoidably prevented from being present, Prof. A. M. Greene, Jr., then read the text of the Code in full. Commenting thereon, he expressed the opinion that the factor of safety of 5 specified for parts other than gears and complete hoisting mechanism was rather low, unless allowance was made for impact. He also believed that the reference to the use of cast iron for brackets should be limited to brackets supporting shafting, and that the specific purpose for using wire mesh should be stated. He desired to ask if a gong that automatically sounds when a crane is in operation would be advisable, and also just what the meaning of "properly" was in the expression "properly lubricated."

In a written communication, R. W. Hicks suggested that the word "approved" used in several paragraphs of the rules for general construction be omitted altogether, or that authority of approval be vested in some organization suitably equipped with apparatus to determine the merits of various devices that are apparently acceptable.

H. M. Mowery submitted a brief written discussion urging that, in view of the slipping hazard, the Code include a statement to the effect that "All tread surfaces, and particularly stair treads, shall be so constructed and maintained that slipping on them will be prevented."

Replying to the queries of Prof. Greene, R. A. Medina[1] stated that the recommendation of a safety factor of 5 represented the consensus of opinion of the Committee. In regard to using cast iron for brackets, he thought it would be well to employ a modifying adjective in order to avoid any misunderstanding. He explained the use of wire mesh in covering openings and thus preventing bolts, tools, etc., from falling to the floor below. He thought an automatic gong, sounding all the time, would have little effect, as the men would soon get used to it and ignore it.

Henry A. Hale, Jr., remarked on the absence of any injunction in the Code as to the type of hook to employ in hoisting a load. In his opinion, the hook should be of an improved type, having, if possible, a handle at the back so that the floormen would not have their hands squeezed or crushed in attaching it to the load. As to manual signals, he thought that they were not apt to attract much attention, particularly when the crane operator was at some considerable distance from the man signaling; and it was very desirable, therefore, that whistles of a proper sort be used in such work.

Prof. F. R. Hutton called attention to several places in the Code where the English might be improved and ambiguities removed. He found that in one place a factor of safety of 5 or 8 was specified and in another that for the brake drum it should be $1\frac{1}{2}$. Either it should be stated that the apparatus designed has the factors 8 and 5, with the exception of the brakes, or that brake factor of safety does not come under the limitation of the earlier paragraph. In the paragraphs dealing with warning signals, it should be made plain that "approved" means "approved by State factory inspectors." With respect to the provision of guards for gear wheels, he was of the opinion that the idea would be more strongly presented by specifying that standard guards should be provided to all existing cranes where practical. Replying to Prof. Greene's query on the paragraph dealing with lubrication, he thought that it would be well to omit the word "properly," leaving it to the foreman to see that the work was done satisfactorily. Referring to the provision that hoisting brakes should be tested, he thought it desirable that the frequency of such tests be specified. He found that in two of the rules the word "hitch" was used. To his mind, while "sling" was a much more general term, he believed it would be better to use both words.

The Chairman, commenting on the remarks of the preceding discussor, thought that the word "hitch" was more comprehensive than "sling," and would include both the operation and the appliance used. But it was well in such things that there be no confusion as to the meaning intended.

A. D. Risteen said that in his opinion the Code should include instructions in regard to starting to lift loads gently. Also, that the highest object over which the crane had to pass should be painted white on the top, so that it would stand out conspicuously against the miscellaneous background of dark objects underneath.

It was stated by H. M. Elder that in the works of the American Locomotive Company the crane operator is signaled to by means of an air whistle; the operator knows the location of this whistle, and looks and sees the man giving the signal. With regard to starting to lift loads gently, it would hardly do to specify this, as it would prevent those having a.-c. crane motors from using them. As to equipping with an approved limit switch, he had to say that his company had experimented with a number of such devices, both purchased and of their own construction, and had not yet found one that satisfied the crane operator and the electricians.

A. H. Blaisdell thought that gongs were often likely to be unheeded and that it was good practice to have the floorman precede the load and warn people out of the way. He believed that a crane out of order or under repair should have a red flag hanging from it; that a crane operator should be

[1] With Independence Inspection Bureau, 137 S. Fifth St., Philadelphia, Pa.

provided with a megaphone, and that there were advantages in using hooks that had been painted white, especially on night shifts.

According to J. W. Upp, it was very evident that both manufacturers and users of apparatus were earnest in their efforts to safeguard the workmen, and to provide apparatus that would give the maximum of protection without unnecessary complications. As a manufacturer he was interested in the discussion, for everything that could be done to make uniform the regulations governing any class of apparatus was a distinct help to the user.

Prof. F. R. Hutton spoke of his visit earlier in the week to Washington, at the instance of the Council, to represent the Society at a conference summoned by the State of Ohio and its officials and the Labor and Factory Commission. Here he was informed that little by little the Ohio State Boiler Code was being withdrawn and that promulgated by the Society being advanced all the time, and that it would be but a short period before the A.S.M.E. Code would be the only one used. The whole atmosphere of the session was so definitely favorable to the incorporation of the technical recommendations of the Society, that it looked to him as if very substantial progress had been made along the line of recognizing that the Society was a body which, by its position and methods of arriving at results, was free from many of the difficulties that often came up to trouble legislators, where they were not sure that business organizations were not behind recommendations with respect to the scientific principles or facts underlying a Code.

In closing the oral discussion as the representative of Dr. Jackson, Mr. Medina stated that the Code had been purposely drawn in a broad and general manner, for the reason that a very specific code would be at the same time very bulky. In Pennsylvania, to his knowledge, no limit-switch device had been approved by the Factory Department, possibly because the Code had not officially gone into effect. Undoubtedly, however, the Department would soon have to say "yes" or "no" to various devices now available. He agreed with Mr. Elder that it was exceedingly difficult to find a limit switch that met the needs of everyone interested, and thought that this was a matter upon which the Committee could well afford to hold a separate session.

MISCELLANEOUS SESSION, WEDNESDAY AFTERNOON

At the second Miscellaneous Session of the Meeting, which was also held in the Auditorium, and at which Dr. Jacobus presided, three steam-plant papers and two papers relating to the flow of fluids were presented and discussed. One of the steam papers, that by Victor J. Azbe, was one of the two papers recommended for honorable mention in the Junior Prize Paper contest for 1916.

MR. PRATT REVIEWS PRACTICE IN THE UTILIZATION OF WASTE HEAT IN GENERATING STEAM

The first paper presented was by Arthur D. Pratt, entitled The Utilization of Waste Heat for Steam-Generating Purposes. The paper dealt with the principles underlying this subject and gave a general survey of what has been accomplished in this line in which it is today possible to generate steam successfully from gases whose temperatures are as low as 950 or 1000 deg. fahr. It also considered the problems involved and the results obtained with waste-heat boilers in connection with copper-refining furnaces, cement kilns, open-hearth steel furnaces, beehive coke ovens, zinc-refining furnaces and furnaces of various types, both generative and non-generative.

Alex. G. Christie said that in connection with the cement-mill work, the noteworthy point brought out in the paper is that there is not only a large reduction of fuel consumption by the utilization of this waste heat, but also a better dust recovery, and in some sections this latter is a question of considerable importance.

The performance of waste-heat boilers described seems to depend largely on high gas velocity being maintained by an induced draft, and that, naturally, leads one to question whether the same principle could not be applied to the standard boiler.

Three written discussions of Mr. Pratt's paper were presented by L. D. Ricketts, Warren B. Lewis and B. N. Broido, respectively.

Mr. Ricketts' discussion was a confirmation of the conclusions of the author regarding two of the installations described in the paper, supplemented by information concerning the amount of power recovered at a typical waste-heat plant.

In Mr. Lewis' discussion was given a description of a plant using waste-heat boilers in which the transfer rate is low, illustrating the other extreme from the plants described in the paper. In connection with the heat-transfer rate Mr. Lewis wrote: "It is true that the velocity of fluids over heated surfaces is a great factor in the transfer rate; it is also true that the greater the velocity the greater the pressure drop, and that the amount of the pressure drop allowable is determined by the cost of producing that pressure drop. Furthermore, the use of a high transfer rate is to reduce the cost of installation, and the reduction so obtained must be sufficiently great to offset the increased cost of power employed in overcoming the excess pressure drop."

Mr. Broido wrote that waste heat is also very often used in Germany to superheat steam; that in cases where, for some reason, superheaters cannot be installed in the boilers, or circumstances require the superheater to be near the engine, independent superheaters are recommended, and in such cases superheaters heated by waste gases are the ideal installation; they do not need the frequent and careful attention which independent superheaters with their own furnaces require. The superheat temperature can be easily and quickly regulated with a damper in the gas inlet. The superheater pipes remain permanently clean outside.

This writer gave a description, with illustration, of a superheater system he had designed and installed for utilizing waste heat from coke ovens and open-hearth steel furnaces.

MR. PIGOTT DESCRIBES GRAPHIC METHODS OF ANALYSIS USED IN DESIGNING STEAM POWER PLANTS

R. J. S. Pigott presented the second paper of the session, entitled Graphic Methods of Analysis in the Design and Operation of Steam Power Plants, a proposal for designing power plants based upon anticipated load curves, which he introduced in the following terms:

"This paper is the outcome of an attempt to standardize to some degree the process of designing steam-power plants. For the past few years I have been engaged practically exclusively in power-plant work, and what struck me, up to the time when this method which I am to present was developed, was what you might call the sloppiness in the methods used in designing steam power plants. Most of the problems have been settled by opinion rather than fact, by inference rather than methodical pursuit and analysis, and inasmuch as we are spending so much time nowadays in systematizing our management in other directions, there is no reason why we cannot systematize and standardize our method of designing a thing like a power plant.

An attempt was made, therefore, to utilize the water-rate curves and input-output curves to a greater extent than heretofore, and to combine them. The method is based on the use of the input-output curve for each piece of apparatus employed in the plant. It is not sufficient to take the isolated loads on separate apparatus to determine what will be the B.t.u. consumption per kw-hr. of the combined plant. If you are to find out what is the change occurring with a variation of load factor or variation of maximum load, you must find out what is the combined variation in units making up the plant, and the only way that this can be done with any sort of simplicity is graphically."

Walter N. Polakov called attention to several other methods than that of using the Willans lines as advocated and used by Mr. Pigott. He said that the limitation of analysis of the prospective working of a power plant which is contemplated to be built for New York City purely by the Willans method has the disadvantage, which Mr. Pigott touched upon himself, that it does not cover entirely other factors, for instance, financial factors, that are just as important and sometimes more important than the thermal efficiency of the equipment of the plant.

Norman G. Reinicker said he had used the same scheme the author proposes without quite so much trouble, by plotting the feedwater demand, as indicated by venturi meter readings for the same load over various numbers of days, and he had found that the effect of putting on another turbine would show up in that curve. This method saves the testing of various machines, and gives a rough calculation, at least. The graphical method is valuable where you can predict the load curve accurately, but in some plants it is hard to predict what may be expected.

James W. Parker said that the assumption had been made that the purpose of an auxiliary power system in a power plant and of the feedwater arrangement is primarily to obtain auxiliary power. The problem, as he saw it, is to heat your feedwater under all situations. At all times it is desirable to generate as much auxiliary energy as possible in the heating of your feedwater. If it is possible during the period of light load to take power for your auxiliaries from the main bus, and during the period of heavy plant load to transfer that from the auxiliary generator, if you have such an installation, to the main bus, you can use your main electrical system as a reservoir for the storage of energy, so to speak, and at all times have the cream of your auxiliary steam turned into auxiliary energy.

Two particular statements of the author brought out considerable discussion. The first of these was that in the Remington plant the average flue temperature for the month was below 400 deg. fahr., and in a case such as this a fuel economizer is out of the question. The second was that in the case of the Interborough plant the economizers were already installed and were removed simply because they obstructed the draft, and the high ratings required meant that they would have to be eliminated for the sake of the draft.

Dr. D. S. Jacobus and Messrs. Albert A. Cary, George H. Gibson, Sherwood F. Jeter, James W. Parker and Arthur M. Greene, Jr., participated in this discussion.

Joseph Harrington took up the question of size of combustion chamber which the author had said he had studied and which he cited as an additional factor in getting the flue-gas temperature down so low.

Albert A. Cary thought that the size of combustion chamber is not a fixed quantity but should be varied according to the amount of volatile matter in the coal.

The author replied to the various points raised in the discussion. As to the question of size of furnace, he said this depended more on how well you were mixing your gases and how long they were allowed to stay at high temperature before throwing them against the comparatively cold boiler tubes.

In reply to Mr. Polakov, he said that in one example in the paper an attempt had been made to make the graphical method cover the financial end. The maintenance and labor were considered and were balanced against the fixed charges.

MR. AZBE MAKES POINTED STATEMENTS IN REGARD TO WASTE OF FUEL IN POWER PLANTS

In a paper entitled Power-Plant Efficiency, Victor J. Azbe called attention forcibly to the preventable wastes in power plants, especially of the smaller or industrial types, these wastes aggregating about 30 per cent and being due to lack of foresight and business ability, improper design, and improper management and inefficient operation.

Summarized, the author's statements regarding wastes in power plants were:

"Lack of instruments to show whether a plant is operating efficiently is responsible for 10 to 20 per cent or more waste of fuel.

"The greatest and most neglected loss in the average boiler plant is from excess air.

"Economizers are not used more generally because their value is not realized. They are economical in small as well as large plants and the initial investment is usually warranted.

"To save the heat wasted by dirty boilers, pure or properly treated feedwater should be provided. It also saves in cost of cleaning and repairs and increases length of life and safety of the boiler.

"Preheating of furnace air is advocated as capable of easily saving 5 per cent.

"Many power plants that have economical prime movers have auxiliaries that are so uneconomical that the efficiency of the whole plant is greatly reduced.

"For industrial and heating purposes low-pressure steam should be used, reduced through turbines, engines or pumps; in other words, exhaust steam should be used. Using reducing valves to lower steam pressures, while not a waste of heat, is a distinct waste of power.

"About the most wasteful power plants are ice-making and refrigerating plants, often because of low load factor and sometimes from ignorance of proper handling of the machinery.

"Among economical prime movers, uniflow engines, locomobiles and exhaust-steam turbines are specially mentioned, and more general use of superheated steam is urged. Pro-

ducer gas plants, gas engines and Diesel engines also should find much greater application.

"More economical plants are necessarily more complicated and require better operating men. One-sided development such as inventing more efficient machinery should be balanced by educating the men to properly handle it.

"The greatest efficiency possible in a power plant is a good deal a matter of proper operation and management. Most power plants could make large savings this way, and there are exceptionally few where some improvement could not be made without purchasing new equipment. To obtain full benefit from the equipment on hand the men operating it must be made more efficient.

"Efforts should be made to obtain a government standard engineers' license law all over the United States, and the men should have facilities for getting the education necessary to meet stricter requirements.

"In agitation for smoke prevention it would be quite as much a public duty to save fuel loss as to avoid public nuisance. Many plants are wasting more fuel since operating smokelessly than before, because of using more excess air.

"It is suggested that The American Society of Mechanical Engineers form a Committee for the Prevention of Fuel Losses and General Betterment of Power-Plant Conditions, to devise ways and means whereby the best results could be obtained."

Mr. Azbe's paper drew out a voluminous discussion, not so much in the way of criticism of the author's statements, but more in the nature of general agreement with his views, the discussion resolving itself into the question of how best to put the author's recommendations into effect.

Practically everyone present agreed that power plants were wasteful, but some attributed the waste to the plant owners, some to the engineers and firemen, and others to some other factor. For instance, Joseph Harrington contended that the question of how you are going to improve the operating efficiency of a power plant was not one of apparatus, of equipment or of instruments, or anything of that kind, but was a question absolutely of the human element. Mr. Harrington considered that an incentive has to be supplied for the man at the end of the line; how this is to be done he did not know, but the matter must be adjusted with regard to all the surroundings and is one requiring judgment, tact and perseverance. He thought that something should be done for the compulsory education of the fireman and that a bonus system of some kind would supply the incentive which they now lack.

Strong exception to this contention was taken by Walter N. Polakov, who considered the trouble to be not with the fireman but with the owner or manager of a plant. How can the fireman do good work if he has not a competent leader? If the management or owner does not appreciate the importance of studying the processes involved, if he does not take into consideration the psychology of his employee, if he does not care to make a small investment for approved instruments, you cannot blame the fireman. In other words, if there is to be an educational campaign with the object of protecting our national resources, primarily fuel, the beginning must be made at the banking end, not in the fireroom—at the money end and not with the coal passer.

Edward A. Uehling took a middle course, attributing waste in power plants not altogether to the owners or entirely to the fireman, but partly to the lack of proper instruments. For example, the first instrument usually put in a boiler plant is a draft gage installed in a flue or stack. This is of no use whatever; the only draft gage of any considerable value is a double differential draft gage put on each boiler to give the resistance through the fire as well as that through the boiler.

P. C. Idell thought that one way to make the paper bring results would be to have an appendix giving summaries from different lines of business, showing how preventable waste had been dealt with and the waste overcome.

A. D. Baldwin suggested that the conclusions reached by the author be brought to the attention of the plant owner; he said he had had the pleasure of meeting both the engineer and the owner, and believed that today the engineer is converted without question.

R. J. S. Pigott, Wm. B. Jackson, E. N. Trump, L. C. Roberts, Albert A. Cary, H. R. Cobleigh, F. A. Wardenburg, Professor Estey, Irving E. Moultrop, Sherwood F. Jeter, Wm. F. Schaller, John Hunter, R. B. Clapp, Wm. H. Kavanaugh, A. M. Feldman, Frank L. Strong and D. S. Jacobus continued the discussion of the paper, which centered around specific cases of performance and the deficiencies of power plants which had come within the discussors' experiences.

In a written discussion of Mr. Azbe's paper, W. S. Gould considered that the author had overlooked the most essential point, namely, the character and quantity of the fuel used. It seemed to him useless to discuss the dollars-and-cents losses in any power plant when nothing is known or said regarding the fuel. Coal is too often considered simply as "coal" and assumed to be of some average quality. This is obviously an error. Illinois coal, to which Mr. Azbe evidently confined himself, varies greatly even in the same district and from the same mine. So it is with coal from every district.

At the close of the discussion of his paper, Mr. Azbe made a motion that the Society form a Committee for the Prevention of Fuel Losses and General Betterment of Power-Plant Conditions, to devise ways and means by which the best results could be obtained in power-plant operation. This motion was seconded by Mr. Hunter, who added to it that the committee be requested to publish from time to time the results obtained in the big power plants of the country, so that the membership of the Society might be kept familiar with the progress of the art.

THE ADVANTAGES OF THE IMPACT TUBE AS A MEASURING INSTRUMENT STATED BY MR. MOSS

The next paper presented was a discussion of the fundamental principles, arrangements for actual tests and formulae for impact tubes, by Sanford A. Moss. This discussion enumerated the advantages of the impact tube over the pitot tube, enunciated the law of the impact tube and gave its proof, deduced the impact-tube law for gases, and illustrated typical impact-tube arrangements. It demonstrated the use of the impact tube in calibrating the venturi meter and the orifice, and also for the exploration of irregular jets and for measuring the discharge of high-pressure air by means of an orifice and impact tube, etc.

In a written discussion, Victor R. Gage stated that the work done on blower testing in the Sibley College Laboratories verified some of the conclusions drawn by Mr. Moss in his valuable paper. In this work it was found that the impact tube gave reliable and consistent results, not subject to error from slight misalignment or from stream lines not parallel to the pipe walls. Difficulty had been encountered in obtaining a satisfactory method for determining the pressure head, or the so-called *static* pressure of moving fluids.

John L. Alden also presented a written discussion agreeing in general with the author's conclusions. He stated that the impact-tube law given is merely a restatement of the law of conservation of energy; in other words, the kinetic energy of the jet may be transferred into potential energy in the impact tube with only the immeasurable loss in the tube itself. Such a conclusion should be expected, as the impact tube is primarily an instrument for measuring energy.

The oral discussion of this paper was opened by Mr. Pigott, who gave his own experience with this class of work. Mr. Pigott said:

"One thing that seems noticeable in the nozzle is that for very high velocities the curve should not be too sharp, so as to induce too much of the stream neck to open still further than the nozzle. It is not so much the effect upon the average velocity ultimately, or upon the rate, as the effect upon the impact, making vibrations in the jet similar to those of imperfectly designed steam nozzles. I suppose in most of the work for which these nozzles were used that would hardly occur.

"I am very much inclined to agree with Mr. Moss as to the valuable feature of the single static hole in the pipe rather than the use of the pitot tube. The pitot tube suffers from two very pronounced disadvantages. One is you are never sure that current is flowing past it in the right direction, except you have some device for accelerating the flow, which invariably smooths out the eddies.

"A further disadvantage is that the static openings have not been decided upon definitely. We have had eighteen designs of pitot tubes, but they seem to have simmered down to the type used by Mr. Trump, with pin-holes in the side, the Taylor type being pretty much discarded; but it is quite certain from Mr. Moss's tests and my own, that the static hole in the side of the pipe will give accurate results on pressure, provided it is not in a place to take the sweep in a curve.

"There is one practical feature which can be overcome. Everybody desires to have a section of straight pipe on which to apply the pitot tube or the disk orifice or anything else that is used, even the venturi meter. That is inconvenient to get in many actual installations.

"It occurred to me when we were anxious to test the blowers installed in the 59th Street Station of the Interborough Rapid Transit Co. with forced draft, that a scheme somewhat like the spacer used in egg boxes would be the thing to kill eddies in a pipe, and that proved to be true.

"You can place a pitot tube or impact orifice right up against the exhaust from such a screen, and you cannot find any appreciable difference over the cross-section of the pipe.

"I have used the same scheme in connection with different pitot tubes for measuring steam. The use of such a screen will eliminate the necessity for having a long run of straight pipe up to the measuring device, whatever it may be—they are all sensitive to the same influences, and even the venturi meter feels the influence of eddy currents on the other side. If you use this device, or give it a straight pipe, the venturi meter does give the most consistent results in the measurement of the amount of steam or the measurement of the amount of water used in a plant.

"Next to that for general robustness of reading would come the disk orifice, and last the various forms of pitot tube, and if pains were used to get an absolutely satisfactory form, and pipes were led to the tube, consistent results might be secured. The fault is not in the pitot-tube device, but in the way it is handled.

"The pitot tube suffers from a disadvantage for steam and water measurements. In a pipe line you must deal with small pressure drops, and the pitot tube has the smallest pressure drop of any of these devices, and consequently any leakage is very much more important in the case of a pitot-tube device than in the disk orifice or venturi meter, which deal with larger pressure conditions. If it were not for that, I think the pitot tube, with the static arrangement in the pipe, could compete in most cases with the venturi meter or the disk orifice."

F. J. Richardson asked Mr. Pigott if he had found any difference in the velocity pressures where the velocity was low or high in using the screen, and Mr. Pigott replied he had not.

In reply to a further question of Mr. Richardson, Mr. Pigott said that where he had no room to make a long radius elbow in a pipe to reduce eddies, he avoided the friction drop by putting in a series of fins or turbine blades to direct the flow.

A form of device used on compressed air through a wide range of velocities was described by G. G. Crewson, who had tried out a number of forms of impact tubes. The peculiarity of this device was that the tube extending into the pipe was in the form of a vee, at a small angle, not over 30 deg., facing the flow. With this Mr. Crewson obtained more uniform results over a long range of flow than with any other types he tried. He attributed this to the fact that the tubes set up more or less disturbance in the flow of air themselves, and by making this long vee he could get the point of impact into the undisturbed flow as near as possible.

Wm. H. Kavanaugh gave an example from his own experience of a straightening device to take care of the swirl of water coming out of a standpipe used to water locomotives.

Edgar Buckingham pointed out that the devices mentioned by Mr. Pigott were quite often used in wind tunnels employed for experiments on the aerodynamic properties of aeroplane models. The egg-container device is used in almost all wind tunnels for getting rid of eddies and making the current as nearly straight as possible.

Regarding the turbine-blade device, in the Goettingen wind tunnel, where a fan is employed for pumping air around in a closed circuit, the place is rather small and there is not much space, and consequently they use in the corners turbine blades to save the space.

MR. REYNOLDS GIVES VALUABLE DATA ON THE FLOW OF STEAM AND COMPRESSED AIR

The fifth and last paper of the afternoon was by Herbert B. Reynolds, on The Flow of Air and Steam Through Orifices. The paper was in two parts, the first covering the flow of air through orifices, including a study of pitot and venturi meters for measuring compressed air, and the second the flow of steam through orifices at low pressures.

Mr. Pigott led out the discussion of this paper by extending the thanks of the Research Committee's Sub-Committee on Steam Meters to the author for the data in his paper, all of which he regarded as exceedingly valuable. He said Mr. Reynolds' paper will add to the data as to which is the best measuring device, but it is certain that both the disk orifice and the venturi meter present pronounced advantages over the plain impact tube for ordinary measurements about the power plant.

In connection with the practical use of the devices described, Mr. Pigott said his own experience tended towards the venturi tube, provided serious eddy currents are not allowed to enter into the up-stream side of the tube.

The disk orifice has one advantage which may offset, in the majority of cases, its chances of somewhat smaller accuracy. Suppose in installing a plant you provide for the maximum load to be obtained eventually in the steam, or compressed air, or what not, and put in a meter service to measure the flow. If you put in a venturi meter you spend an item of $200 or $300 in a tube for a 10- or 12-in. line, and the readings, after the first few months or a year, are very low and within accurate range of the recording instrument. The disk orifice for this purpose is particularly convenient, in that, in a couple of hours, when the vacuum is down, you can substitute for one size of orifice another size, and have the same recording instrument, and get high accuracy for low loads.

E. D. Thurston asked the author if he had had any experience in using venturi meters in parallel, not necessarily putting two on at a time, but a bank of venturi meters between two headers used in different machines as the demand for air varies. He himself had once used four tubes in a bank and found that with three shut off there was a record on the manometer indicating a slight pressure at the throat.

Frederick N. Connet explained this by saying that if there is a dead end beyond the venturi meter, a dead end at pulsating pressure, there is a constant vibration of the air back and forward from the throat, and a slight differential will be obtained, although there is no flow.

Mr. Connet described some experiments made at Providence in which air was measured in a somewhat simpler way than that described by Mr. Reynolds. The feature of these experiments was a method of measuring the pressure drop through the venturi meter by an electrical method whereby decrements of pressure could be measured with much greater accuracy than could be done by watching a large pressure gage.

A. G. Christie said he had checked the results in Mr. Reynolds' paper against some careful tests made a number of years ago on some Taylor tubes. The coefficient for the Taylor tube placed at the center of a 12-in. pipe was practically 0.8, and as far as he could interpolate from the curves in Mr. Reynolds' paper for a 2-in. pipe, the latter's value was 0.77. The similarity in the value of the two tests on entirely different sizes of pipes struck him as remarkable. In Mr. Rowse's paper in the Transactions of the Society for 1913, the coefficient for an impact tube placed at the center of the pipe, and using a hole on the side of the pipe for the static, was the square root of 80.

Another point in the paper which impressed him was the statement that below a certain number of cubic feet discharge the readings of the pitot tube were unreliable. He checked that over, and estimated that the velocity at which the readings became unreliable was practically 30 ft. per sec. He also checked the same thing in Mr. Rowse's work, and found he was getting results with considerable accuracy as low as 20 ft. per sec.

The question of the swirling effect in a tube was taken up by E. G. Bailey. He said he did not think it was generally appreciated how much this effect amounts to; cases had been found where, in the center of a pipe, at certain velocities the velocity is only 15 per cent of what it would be expected to be with a true elliptical flow, showing the centrifugal force due to the helical motion in the pipe to be enormous. When you get that into the throat of a venturi, there is nothing to stop the helical motion; in fact, its angular velocity is accelerated, giving an impinging force against the opening.

S. A. Moss thought the author had really presented data that showed the venturi meter to be much preferable to the plate orifice, and gave his reasons for arriving at that opinion.

The mathematics of both Mr. Moss's and Mr. Reynolds's papers was discussed by Edgar Buckingham, who said that many who are not familiar with the formulæ given, and similar ones for thermodynamic flow, have a higher opinion of them than is justified. For instance, essential conditions to the validity of Mr. Moss's formula for the velocity of a jet do not exist in practice. In such a formula so many assumptions have to be made that the ideal case to which it applies is far different from most actual cases, and therefore it is not surprising if the formula is not justified by experimental results. The moral is that the engineer, who often despises theoretical work, should not despise the theoretical formula, because he is applying it to a case to which the physicist knows it is not supposed to be applied.

TEXTILE SESSION, WEDNESDAY AFTERNOON

The Textile Session of the Annual Meeting of the Society was held on Wednesday, December 6, at 2:30 p.m., under the auspices of the Sub-Committee on Textiles, Charles F. Plankett officiating as Chairman. Three papers were presented at this Session, the first of these being one by Arthur N. Sheldon, entitled Heat Transmission through Various Types of Sash, in which the author gave particulars of experiments made with different types of wood and metal sash, both with single and double glazing, and of others to determine the cause of condensation in double-glazed sash and means for its prevention.

In opening the discussion of the paper, F. J. Hoxie inquired if any experiments had been made where two sash were placed some distance apart, and the space between them heated. Theoretically, he thought that it might be a good idea.

William Dean stated that he had found that one of the difficulties manufacturers experienced was that the holes in the sash let in dirt, which accumulated on the inside and made it almost impossible to clean it without taking out the glass. He believed that most of that dirt came from the inside. If a hole were put in the outside, with the colder air coming in from that side, he thought the condensation on the inside would be materially lessened, if not done away with. In the Bates Manufacturing Company's mill a double-glazed new sash was used, with ventilating sections in the sawtooth, which could be opened at times, and he believed when they got the colder air inside that it lessened the condensation more or less on the interior surface, which would bear out the result of Mr. Sheldon's test, that an outside opening would be preferable to an inside; but that presented the problem then of keeping the dirt and dust and water out, keeping it from getting into the air space, which no doubt could be worked out.

Charles H. Bigelow inquired to what extent double glazing was being used in factories, and also how much condensation there would be on the inside of a concrete roof, which was also likely to cause trouble, and what steps could be taken to prevent it at a reasonable cost.

In reply the author said that double glazing was used to quite an extent, not to so great an extent with steel as with wood, on account of the additional cost of double glazing

steel sash; and that additional cost, as described in the paper, sometimes worked out to a disadvantage, and it did not pay to do it. No doubt there would be a saving on wood in this locality of about 32 per cent, and there was no question about that being a paying investment. As regarded protecting the concrete roof, hair or cork insulation could be applied to reduce the heat loss.

William W. Crosby recalled particulars of a building of considerable size where steel sash were double glazed with about 1/4 in. of space between, and only about two-thirds of the usual amount of radiation was supplied, and only about one-half of the usual amount was in use on the coldest days. The building had a very cold exposure.

W. R. Cobb[1] stated that his firm had probably done more double glazing than any other in the country, and for twenty-three years had done more or less experimenting along that line. There was no doubt a great saving in coal by the use of double glazing. The principal objection to it was the accumulation of dirt between the two layers of glass, and if he were building a factory, he would want the double sash at least, so that one could get at all sides of the glass to clean it. His firm built hotbeds with double-glazed sash, and in the coldest weather they required no mats or shutters.

R. W. Weed desired the author to state his experience in comparing a double-glazed steel sash with a double sash. He had found that the great heat loss was due not to conduction through the glass, but to leakage around the cracks, etc., and that the heat losses would run around 80 per cent, whereas that due to conduction would be only about 15 per cent. For that reason he believed that the double sash was preferable to double-glazing sash, because it furnished a double insulation.

In reply the author stated that there was no doubt that two windows, a storm window outside of the regular window, would prove more beneficial as far as heat losses went than double glazing: but the double glazing was less expensive. In Canada they triple-glazed, with three lights, in refrigerating plants, etc.

D. Seabury stated that the double sash had an advantage where it was desired to put prism glass on the outside, as it gave a chance to keep it clean.

The author, in reply to a question by the Chairman, stated that the tests on heat transmission were made before the holes were put in the lights of glass. Later, they bored the different lights of glass with these holes, and then experimented further with regard to condensation, regardless of heat transmission. The holes were only about the size of a lead pencil, and placed near the bottom, so there could have been but very little heat loss through them.

A NOVEL METHOD OF STUDYING SPONTANEOUS IGNITION DESCRIBED BY MR. HOXIE

The second paper to be read was one by Frederick J. Hoxie, entitled Spontaneous Ignition Studied by Means of Photographic Plates, in which the author stated that various substances undergoing slow oxidation gave off hydrogen peroxide, which latter was capable of making a developable image on a photographic plate, the intensity of the image being roughly proportional to the rate of absorption.

Opening the discussion, Ira H. Woolson asked the author if he had discovered any difference in the activity of charcoal due to the variety of woods from which it was made; whether wood that contained resin, for instance, had any different activity upon the plate, as compared with the wood that did not contain resin.

The author, in reply, stated that he had found certain varieties of wood were more active than others, but that some other specimens of the same variety were not active, so that he was not inclined to generalize very strongly on that point.

C. P. Beistle[1] stated that charcoal made from beech, birch or maple was more liable to spontaneous ignition than that made from other woods. He thought the real cause of the risk in charcoal was due to the process rather than to the wood used. Most charcoal nowadays was made as a by-product of making wood alcohol and acetate of lime, and almost invariably retained a good deal of volatile matter. Formerly, charcoal was burned anywhere from seven to fourteen days, and was very hard and very dense, and almost free from spontaneous heating.

Leonard Waldo stated that he had had a case come up of an ignition of flash powders, and was very much bothered to find some simple way by which the rate of oxidation of magnesia, for instance, could be determined, so that it could be known what was taking place. He desired to learn whether oxidation of powdered metals, either with or without the presence of an oxidizing substance, would be shown by the author's orthonon plates, by simply putting the metal in contact with the plates and letting it stay there awhile exposed to the air; also whether there were any publications that gave extended lists of temperatures of ignition. If the gradual oxidation of metal could be shown, either in steels or lighter metals, by simply putting them on a sensitized plate, and developing the plate later, this would be a most important contribution to the technique of oxidation.

The author, in replying, said that he had never heard of any experiments being made on magnesium, but knew of no reason why they should not be made. In regard to the ignition points of different substances, there was quite a lot of information available. To say, for example, that the ignition point of wood was 500 deg. did not mean anything, for the reason that that particular wood had been exposed to light, whereas if it had been strongly charred, the point might have been changed materially.

Christopher H. Bierbaum desired to learn whether the photographs had been made by placing the substances in close proximity to the plate, or whether lenses were used, and also what plates. One question raised was whether the oxidation actually was in direct proportion to the actinic effect upon the plate. The chemistry of it was that we started with bromide of silver on the plate. The bromine, being a strong oxidizer, produced that salt in the presence of the actinic ray, so that it would readily change from a bromide to an oxide. That was done during the development. Was it not possible that it was all entirely due to the ionic potential of the substance? The question was whether it was actually due to actinic rays or vibrations in the hypothetic ether, or to the presence of ionic emanations, or a chemical change.

The author replied that the action was purely a chemical one. Apparently most any rapid plate could be used, but a slow plate could not be used successfully. Some exposures had been made on Lumière X-ray plates, a very rapid plate, and some were made on the standard orthonon, also a rapid plate, but in no sense were they photographs. The first impression was that this was a radio-active phenomenon, that it was an emanation from some substance, very much like the X-ray, but this had been found to be incorrect. One experi-

[1] With Lord & Burnham Co., 30 E. 42d St., New York.

[1] With Bureau of Explosives, American Railway Association, 75 Church Street, New York.

ment tried was to take a glass and put it over the object which was giving off the emanations, but there was nothing to indicate that there was really a substance coming off. If that had been a remarkably short wave of light, it could possibly have had a similar effect. He thought the active agent present was hydrogen dioxide. It was well known that hydrogen dioxide, when put in contact with a photographic plate, would make a developable image. The active agent might possibly be some other form of active oxygen, but ozone, without the presence of water, did not give this action.

Mr. Bierbaum thought that in the experiment made with the covered glass, if the author had taken a cover glass made of quartz crystal, and found that in one case he had the effect and in the other case he did not, he would prove it due to short waves, because the extremely short actinic waves would pass through quartz and produce actinic effects which were not possible through glass at all. He thought the author's experiments on this point were very interesting, because they seemed to indicate that the presence of ionic emanations produced the same effect as the short actinic wave.

The Chairman said that, in the interest of the cotton manufacturers, he would like to ask the author whether he had discovered that there was a material change in cotton fiber by the slow oxidation mentioned in the paper, which it was said is going on at all times, sometimes being on the outside of the bale, and having a moisture and temperature differing from that in the interior of the bale. And whether it had been found true that after a long time the staple was weakened on account of the oxidation which had been going on, possibly for years, before the bale had been opened for use.

The author, replying, said there was little doubt but what the strength of the staple had suffered. A common sight in almost any cotton mill, where pieces of sheeting were used for window curtains, was that where the moisture touched a curtain it turned brown, and had every appearance of being as thoroughly burned as if it had been in contact with hot iron; this was doubtless due to the oxidation which had taken place because of the combination of moisture and light. He had often found cotton and linen, linen particularly, which had been subjected to a comparatively low temperature, after a good period of years, that had every appearance of being as thoroughly charred as though it had been in contact with a hot stove. Doubtless that was due to the amount of moisture it contained. Mr. Hartshorn, in his classical work on moisture in cotton, mentioned the fact that cotton which had been submitted to changes of moisture and dryness for a considerable length of time seemed to lose its property of absorbing moisture, and of following the law which he had shown to exist for other cotton. Last year Prof. Naumberg, of the Institute of Technology, had made some further experiments along that line, in which he collected some old cotton that had been exposed to the air for a long time, and found that it reached an equilibrium to the atmospheric moisture at quite a few per cent less. Apparently, this was not a question of fungus growth, but was purely a question of the chemistry of cotton.

The Chairman remarked that cotton eighteen or twenty years old was now coming on the market because of the present high price. The question was whether there had been a very serious deterioration in the interior portions of the bale, by reason of combustion that had been going on slowly, but over a long period of years; whether it was really deteriorated so that it would be unfit for use, or suitable for the uses for which such cotton would be apt to be used. He also desired information as to cotton fabric piled in storehouses in bales. Many times discoloration was found on the part toward the windows. Was it true that there would be a deterioration of the strength of that fabric, and would the color indicate that the fabric itself had been injured by its storage, where it had received the rays of light?

The author, as to the first question, was inclined to believe that the staple would be found to be weaker, and, under certain conditions, considerably so. He thought that if the discolored cotton were boiled in caustic it would become as white as ever, but there would be less cotton, and that the process could be repeated until there was not much cotton left. Doubtless the action had something to do with the temperature. If the storehouse were kept at a very low temperature, it would no doubt reduce the action, but to what extent he did not know.

Replying to inquiries as to how the substances were exposed, he said that in the case of articles of wood they were placed in direct contact with the plate, but the oils were kept a little distance away, to avoid getting oil spots on the plate. The nearer the object to the plate the stronger the action was, and therefore it was desirable to get it as close as possible.

In regard to the photograph with a part marked "screened from sunlight," he would say that he took a piece of wood into a semi-dark room, so that the amount of actinic light was negative, and planed off the surface which had already been acted on by light. He then placed on it a piece of tinfoil which had a square hole cut in the center, and then placed it in the sunlight. Where the tinfoil was the sunlight did not strike the wood. He then took this into the dark room and removed the tinfoil and exposed the wood to the sensitive surface of the plate, and then developed the plate. The part of the wood which had been screened from the sunlight had practically no action on the plate, showing that it was a peculiarity of the wood which had been acted upon by sunlight.

Mr. Bierbaum stated that if the author had proceeded to expose part of a diamond to daylight, and then produced the same thing—he understood the diamond would have the same effect — the part exposed to sunlight would have a similar effect, that is, its actinic effect on the photographic plate would be the same. In that case there would be no chemical change, it would be purely an emanation.

MR. PERKINS DISCUSSES METHODS OF ELIMINATING VIBRATION IN TEXTILE-MILL BUILDINGS

The final paper of the Session was then presented by G. H. Perkins, its title being Vibration in Textile-Mill Buildings. After stating the nature of vibration in textile-mill floors, the author dealt successively with the causes of such vibration, the objectionable effects it produced, means for its elimination, and precautions to be observed when textile machines are mounted on rigid floors.

Charles H. Bigelow, in opening the discussion, recalled one building, erected about nineteen years ago on piles, that swayed back and forth in time with two 1200-kw. engines, 75 times a minute, so much so that the window weights could be heard to rattle back and forth in their casings. The actual movement of the corner of the building in relation to a pile of lumber 50 ft. away on a marsh was 3/8 in. When the two engines were running, the motion would come to be a maximum, and then would cease as the engines opposed each other. In another building he had found a 4200-hp. engine, under which the whole foundation moved around about 1/2 in.; this was stopped by anchoring the foundation to other parts

of the building. It was certainly a serious matter. How much actual power was lost in the machinery he could not say.

W. W. Crosby asked that further information be given by the author as to the curves shown in the paper, and that the plane of vibration be defined. He also desired to know whether the looms were driven by motor or by belt. He would say that he knew of a certain concern which had several foreign mills, built of rigid construction, with steel beams and brick arches, and they had hesitated about building a new mill with heavy beams and plank, as we did our slow-burning construction, because they thought it would be so full of vibration that the machinery would not last. After several years' operation, he had been told that as yet no undue wearing of parts had been detected which might be ascribed to vibration.

Henry A. Hale, Jr., stated that it had been found that the accidents to employees in spinning and weaving operations were largely due to carelessness. He thought nothing engendered carelessness more than fatigue, and if by eliminating vibration this could be cut down, and thereby the number of accidents, it appeared to him that the resulting economy was something that could not be overlooked. Additionally, the effect of vibration on operators was to slow them up in their work.

Ira H. Woolson inquired of the author whether vibration was a matter of common complaint with the operators—whether it was physically objectionable to them.

W. W. Crosby stated that he had heard of employees making serious objections to working on floors which were too rigid. Help that had been working on wooden floors had raised all sorts of objections because they had been put to work on concrete floors.

The Chairman stated that he had learned from the author of one mill where they still had, after fifty years, some wooden frame looms, and those looms were heaving in all sorts of ways every time the lathe moved, and still the treasurer of that mill said he was getting the best cloth from those looms, better than from the modern heavy looms, and that one could see the loom heave at all times, with every oscillation of the lathe. The Pemberton mill, in Lawrence, which collapsed completely in 1863 or 1864, was a very rigid building and only three years old, and it collapsed completely; and it was a question whether any building had been known to collapse from vibration. It was a rather interesting point, and the building apparently must have been well constructed to have shown as much rigidity as it did on all the floor surfaces in the mill. There were peculiarities arising from this question which made it an exceedingly interesting one. It was particularly important to the cotton and other textile industries to know whether to be alarmed by the oscillation that they found in their mills, or to know if their mills were too rigid that they might collapse, or that they might not get any better results, even psychologically.

In a written discussion, Maurice Deutsch[1] stated that it was often asked why English mills made such good yarn out of poorer cotton than used in America. The answer to this, he thought, lay in more rigid construction of the mills and the special attention given to the cushioning and arrangement of machinery. In a sawtooth weave shed in England, he knew of looms standing on flagstones and running at 220 to 225 picks per min. Just how rigid a structure should be, would depend upon the material fabricated and other conditions, but for textile mills he thought rigidity of structure should be sought for, and the detrimental effect of vibrations minimized by the proper application of composite absorption material between the machines and the structure.

It had been found that vibrations having a frequency of about 15 per sec. and a double amplitude of about 0.002 in. had generally been the cause for complaints made by occupants of houses in the vicinity of railway trains or certain types of machinery, also that a frequency of about 7 per sec. and a double amplitude of 0.0012 to 0.0016 in. could just be felt.

The important question of the human susceptibility to vibration was one to which little study had been given in this country. In England, however, some very interesting observations had been made by Mr. Digby and Capt. H. R. Sankey.

How far beyond the limit of perceptibility the vibrations recorded by the author were, might be somewhat appreciated when compared to the observations of Prof. E. E. Hall, of Berkeley, Cal., that when the frequency was 2 per sec. the double amplitude had to be approximately 0.004 in. before it could be felt. From many observations made in buildings the discussor had found that amplitudes as low as 0.002 in. when the frequency was over 10 per sec., were a genuine source of annoyance to occupants. It had been found that vertical vibrations damped out much more rapidly than did horizontal. The latter were more apt to produce detrimental effects to the structure, while the former might produce the greater effect on the machines and fabric.

Morton C. Tuttle,[1] in a written communication, gave numerous interesting and instructive particulars of experiences brought out in the course of the investigation of the effects of vibration now being conducted by the Aberthaw Construction Company. So far as the investigation dealt with textile mills, it seemed to show that vibration tended to increase the power requirements of machinery and to limit the speed of operation and hence the output. There was a certain diversity of opinion among the correspondents reporting, but this, it appeared, depended upon the type and character of building. It was made quite evident, however, that the most serious cases of vibration were found in old buildings or those unsuited for use as textile mills.

The author, in closing the discussion, replied to Mr. Crosby's queries, stating that the records given in the paper showed longitudinal vibration only. He gave particulars regarding the type of drive used for the various banks of looms, and called attention to the record taken at Station 1—about 50 ft. from a group of electrically driven looms, which showed that the vibration was transmitted undiminished in amplitude through the floor.

As to the question asked by Mr. Woolson, in all cases that had come to his attention, new help generally found vibration quite objectionable, but after a time they became accustomed to it. There were certain mills to which he went occasionally where he would not care to work himself for any length of time, and he felt a certain apprehension just in passing through them.

If he had understood the discussion of Mr. Deutsch correctly, that gentleman had indicated that if we should decrease the amplitude by making a more rigid building, it would be possible to increase the frequency: but he thought if Mr. Deutsch attempted to run 104-in. looms at more than 100 picks per min., he would be in trouble, no matter what sort of building he was in. It did not mean that these looms could be run up to 200 simply by installing them in a rigid building, such as they had in England.

TOPICAL DISCUSSION ON MANAGEMENT

It is the custom of the Society occasionally to hold meetings without regularly prepared papers, for topical discussion and the interchange of experiences. Such a session was arranged by the Committee on Meetings for Wednesday afternoon of the Annual Meeting, on Recent Developments in Industrial Management. There were three other sessions in progress at the same time, and it was necessary to assign to this session the small meeting hall on the twelfth floor of the building, seating less than one hundred. By actual count there were one hundred and twenty-five present throughout the afternoon, with a total attendance of perhaps two hundred, and much of the time there was not even standing room,—this in evidence of the very general interest in the subject of management.

COÖPERATION OF WORKMEN, BY E. E. BARNEY

The first discussion was by E. E. Barney, of the Remington Typewriter Company, on How to Secure the Coöperation of Workmen. He said that coöperation must mean more than "working together"; it must mean working together with common interest toward a common end which, when attained, should be mutually beneficial. In analyzing his subject he made a unique comparison of the laws of physical science with those of human nature, referring to the following phenomena and properties of matter: Density, specific gravity, heat, light, magnetism, and electricity.

For example, he said that *density* in physics referred to the mass of a body. Among mankind we also had density,—the mass,—the untrained, unskilled, the hopeful and the discouraged: a mass welded together, but alive and struggling, like a bar under tension.

Heat, he said, was positive; it caused most substances to expand. "Let us try the effect of heat or warmth on our associates, the workmen. Warm them with human interest. . . . Men are susceptible to sincerity, but often are slow in absorbing the warmth of sincerity. Like the metal which expands when plunged into the fire, they often shrink and resist the glow and warmth for fear of the motive which may lie hidden behind it."

Magnetism was a force easily likened to the qualities necessary in coöperation. One could not expect a workman to lead in the spirit of coöperation—he had not been trained that way. Too often the magnet of plausible argument which at first attracted him proved a repellant force when the real motive of selfishness became exposed.

Electricity was a subtle power which demanded control. It was the central conscious or unconscious thought which affected our acts toward those whom we would control or influence. In the development of organizations, cables were led from the central power to points where the power was needed. With ideas and ideals as the central power it was possible through proper mediums to convey these great distances; but make one break in the direct line, i.e., let one man of the direct organization fail to transmit the current of standards sent out from the head, and we would fail in delivering beyond that point the vital fluid on which depended the success of our hopes.

In conclusion, the speaker contended that to secure the coöperation of the workmen one must, as in the old colored woman's receipt for rabbit pie, "first cotch your rabbit,"—the mass,—the men. One must select the individual and classify him according to his ability; warm him with the interest he deserves; enlighten and train him to the advantage of both; attract him by fairness and consideration; and make sure that one's organization was carrying the proper message of the spirit of coöperation to and beyond the workmen, who were the most valued asset of any industry.

THE VALUE OF HUMAN RELATIONSHIPS IN INDUSTRY

In discussion of Mr. Barney's remarks, R. B. Wolf said that in scientific management one must study the forces which had been outlined, scientifically. When dealing with men and attempting to direct them in these operations, we were dealing with something in which the realm of facts found in natural law did not exist; in other words, man was a free agent. In dealing with material things there was a realm of facts which conformed absolutely to law, as in the conversion of water to ice at thirty-two degrees. We knew that such things always happened in that particular way. There were, however, many ways by which water could be reduced to a temperature of thirty-two degrees, as by carbonic acid gas, or by moving it northward to a colder climate. To obtain such change in conditions the will of a human being was essential. Man was the instrument for creating the conditions through which the natural law could operate, and must be reckoned with in that aspect and given more freedom and liberty for the exercise of his creative faculties.

W. S. Rogers, who said that for "twenty-eight years he had been a member of our venerable Society," but nevertheless was the "youngest one present," spoke at length in a reminiscent and anecdotal vein. Throughout he emphasized the importance of the *man* as an asset in organization, and gave many illustrations from his own experience to show that success and contentment for all concerned had come from a consideration of the human factor.

Thirty years ago his friend and preceptor, John E. Sweet, had built a special machine which the speaker went to see, and after inspection remarked, "It is a success." "No," said Uncle John, "I have made a big mistake. I should have built a man first."

Mr. Rogers related how in 1896 he went to Cincinnati on a two years' contract to take charge of an "old scrap pile of a plant" which was losing money. At the end of the contract they were making twenty per cent dividends, and the owners complimented him highly for the things developed by a mechanical engineer. As a matter of fact, he "had not used any mechanical brains whatever." He had simply studied and experimented with the men. He had not added a single new machine nor made a single new jig. Neither had a man been discharged nor a man added to the payroll.

Twelve years ago he had the desire of his life in a plant where he did not have to ask a man on the board of directors what he should do. The cash capital "was $14.95 and they could not borrow a cent." Today the plant was a great success and its stock was selling for "six times its original par value."

This was accomplished through coöperation with the men to make them feel that they were a part of the organization. Houses were put up, which they were assisted in buying. Profit sharing was introduced, and payments were made monthly, a plan he had learned in England. A shop legislature was introduced, with a House which met in the superin-

tendent's office and a Senate in the manager's office. In case of necessity they met jointly. No man could be discharged without bringing the case to the House, and if possible another place would be found for him in the works.

A special training school for employees was started. Charts were introduced in the House for showing the output of production. Once a month there was a meeting of the entire force, at which the different men or departments were shown where money was lost; and how such loss took money out of the other partners' pockets and how it might be rectified.

The trend of Mr. Rogers' remarks was that no matter how fine the buildings, how modern the machinery, nor how refined the system, all were worthless unless the man was considered of the highest importance and brought into the closest possible union with his employer. Buildings, machines and systems could always be replaced; but good labor must be evolved, and once destroyed takes years to replace.

GRAPHICAL CONTROL ON THE EXCEPTION PRINCIPLE. BY FRANK B. GILBRETH

In introducing the subject of the use of graphical charts in industrial establishments, Frank B. Gilbreth outlined the possibilities of eliminating waste through the use of the exception principle in management. No cost system, nor chart system, can be considered really satisfactory unless it fulfils the following requirements; i.e., it must determine and show:

1 What the quantities of individual outputs should be (prophecies of outputs).
2 Prompt records of individual outputs.
3 What the costs should be (prophecies of costs).
4 Prompt records of costs.
5 Causes of fluctuations and deviations of outputs and costs from prophesied outputs and costs.

It was obvious that the foreman, or other functionary, should see promptly all the records of output in his particular department. The time of the over-foreman, however, who might have several departments under him, was too valuable to attempt to examine all the records of all the men, and he should be supplied with information in concise form, such as was often furnished by "averages."

While ordinary averages had their use, their value was slight compared with the benefits which might result from concentrating the same attention on those individual cases which brought the average away from the ideal.

From causes marked on the chart it might be found that the worker's slow output was due to the lack of proper tools; to the routing system having failed to give him proper materials in the right quantities, in the right sequence, at the right time; or to the man's not having been properly instructed; to there having been an unwise selection of the man or the machine, or both, for the particular job, etc.

The worker, also, would be more careful not to do anything which was not expected of him, because he would know that the exception would surely be noticed by those higher up and would interfere with his chances for promotion or transfer to work of a more desirable kind. Knowledge that they might be investigated would create a tendency on the part of the foreman and the workers to coöperate with others whose work affected theirs, or who in turn might be investigated.

These charts, with the "exclusion zones," enabled the executive to eliminate the motions required for general oversight and inspection until a place on a chart was brought automatically to his attention where he could actually help those below him and furnish them with better instructions for handling their work more efficiently; or for making such changes as would naturally result in promotion, or the selecting or shifting of individuals better fitted to do work elsewhere. The possibilities of relieving the executive of unnecessary motions and of enabling him to be more efficient in his own work were not exceeded in the case of any manual worker.

STANDARDIZATION IN INDUSTRIAL MANAGEMENT. BY SANFORD E. THOMPSON

In introducing the subject of standardization, Sanford E. Thompson said that whereas apparatus and objects used in manufacturing had been extensively standardized, machinery had been improved, plant layout perfected, and in many cases the personnel of the managing force carefully selected, the standardization of the processes of manufacture were as yet almost ridiculously crude. We found laborers selecting their own shovels regardless of the class of earth, or the adaptability of a long or short handle, and we saw them using shovels in whatever way they saw fit. Workmen were not only allowed to select their tools, but allowed to utilize their material and to do the job in any way they chose. It could not even be said that they used their "initiative"; they simply followed in a rut, often a very deep one, worn out by their predecessors on the particular job in the particular shop.

Those who had given thorough consideration to modern industrial methods appreciated that there was one best way to do each job and that every operative ought to handle every piece of work by this standard method. Some might not agree with this, perhaps, because they emphasized too strongly the difference in make-up of different operatives; but the tendency was towards standardization. Not until we arrived at standards in methods of performing individual operations, as well as standards for the layout and general handling of the work, could we hope to have a properly managed plant.

Referring to stop-watches as an element in the study of methods, the speaker said that while they were a necessity for standardization, if they were used simply to find the time in which an operation was being performed, instead of the time in which it ought to be performed, they were comparatively useless. It was the getting at the proper methods and determining the proper tools and machinery by scientific study that meant real saving in time and material.

For example, in piece work where a level rate was maintained employees were all following the slowest and poorest man, and the management was helpless because it did not know the best or the quickest way. By giving definite instructions in all classes of work, just as was being done in many cases of machine-shop work, it was possible for the majority of the men to learn instead to work at the speed and by the methods adopted by the most highly skilled.

In certain kinds of work, standardization might be practically the whole thing. It was amazing how standardization simplified certain processes which had been considered so variable as to make it impossible to produce uniform results. A good example of this was in the cooking of sulphite pulp. The wood came to the digesters, which were large steel tanks, perhaps 12 ft. in diameter by 30 ft. high, where it was cooked under high pressure in bisulphite of lime liquor. Formerly it was the universal belief of all pulp manufacturers that on account of variations in moisture, differences in quality of wood, variations in the character of the acid, and many other variables, the largest of which was designated as "pure cussedness," uniform

lengths of time for cooking and a uniform product were impossible to obtain. Cooking, in other words, was an occult process known only by a few experienced men, and even with those experienced men operating the digesters, variables were impossible to allow for. Now, as a result of standardization which involved the manufacture of bisulphite liquor as well as the cooking process itself, it had been found possible to produce pulp from ordinary wood coming from various sources, which from the paper mill standpoint was practically uniform in quality, and to bring off the cooks at lengths which varied by not over five or ten minutes.

The standardizing in the digester house consisted essentially in determining the curves of pressure and temperature which should be followed during the process of cooking, giving these definite standards to the men handling the digesters and requiring them to follow the standards set. In order to obtain the most uniform results, however, it was found advisable, and very effective, to make definite records of just how much each cook varied from the given curve and give a bonus for maintaining the curve. Similar plans had been found very effective in other classes of work, illustrating very clearly how useful was the form of bonus payment for maintaining quality at a high standard as well as in other cases of maintaining standards of output.

A SPLENDID EXAMPLE OF COÖPERATIVE AND SERVICE WORK FOR EMPLOYEES

A. J. Baker, who was in attendance at the Annual Meeting as representative of the Cincinati Section, quite won his audience by the pleasing account which he gave of the Employee's Service Work of the Cincinnati Milling Machine Co. He said that he had conferred with a friend about the relationship between manager and employee, who remarked that he believed the main function of the people who adjusted this relationship was to arrange so that the employee could take home twice as much money as he did before; and in thinking it over he admitted that it came the nearest of anything to summarizing the whole result that it was desired to attain. If the amount in the pay envelope were doubled, everybody was happy; but if substantial progress were not made in this direction, no matter what the system, nothing would really have been accomplished.

At his plant the combination of the premium and bonus systems was used, although he believed their characteristics were so obscured that the founders of these, Mr. Halsey and Mr. Taylor, would disown them.

With this arrangement there was an inducement for high-grade men who did not content themselves with just reaching the standard time set, as well as for the standard man who just measured up to the time-study limit; and for the man who had secured his job under false pretenses and who was not worth the money he was being paid, there was an inducement to work up to the point where he *was* worth the money. As a result it has been possible to hold the organization together in a very satisfactory way during the period of labor trouble that has been expensive for Cincinnati manufacturers. That, he said, was the starting point of the special relations that had been established.

In the study of men and conditions, it was decided that the physical condition of the employee became a most important element, and a physician was hired and established with headquarters, who at once assumed the position of intermediary between the officers of the firm and the men in the shop. It was aimed as far as possible to return somewhat to the old feelings and close relations that used to exist between employer and employee, but which it had often seemed impossible to maintain under present industrial conditions.

It used to be that the apprentice was a member of his employer's family and the relationships were, of course, satisfactory. At the other extreme was the paternalism now practiced by some of our large organizations which, Mr. Baker felt, was not entirely in keeping with the institutions of this country, particularly if it extended to the time outside of office hours. His firm limited itself to investigation of the man during shop time, and, since it was difficult for the president, vice-president and other officials to attend to their business duties and also to act as the intermediary who would bring about the important personal relations which were desired, this trust was given to the physician, who, by virtue of his office and the character of his work, would be a very suitable and satisfactory man for the purpose.

It had proved that as many as 250 cases were sometimes treated in a day in a plant employing only 1600 men. They did not come necessarily because of serious illness or injury, but often because of minor things with respect to themselves or members of their families. The physician was thus close to the men and was often consulted on matters not related to personal health.

Among the matters investigated was the question of food. Oakley, the suburb where the works are located, had inadequate lunch facilities, and the men who did not live in the vicinity either brought a lunch with them, which they ate cold, or else went out to a saloon. After analyzing the situation it was decided to purchase a complete set of utensils, refrigerators, counters, etc., which were turned over to the employees, who were told to use the equipment for operating their own lunch room. They appointed a committee to purchase their own food and set their own prices; in short, they had a representative organization with which the management was not connected in any way, and it was extraordinarily successful. Starting with a patronage of 60 or 70 a day, there were now about 450 who secured their lunches there.

Here again the physician came in, for he was able to suggest to the men the dietetic value of certain foods and to assist them not only in securing good nourishment but in reducing the cost. By this means the health of the employees undoubtedly had been helped. A mutual-aid association was also started which the firm was supporting financially, but which was run by the employees and to which they contributed through a special fund for sickness benefits. Here again the physician, having the confidence of the men, was in many cases able to forestall serious illness.

It was surprising how many of the men were found to have incipient diseases unknown to them, which the physician discovered and was able to treat successfully because of their early discovery. Further, he could very frequently state to the superintendent that a certain man was not physically fitted for the kind of work he was doing, which would lead to his being transferred to a department adapted to his condition, thus saving the money lost in breaking in a new man, and winning the gratitude of the one who was transferred. No man was discharged without having the medical department look into the situation, and it must also be with the consent of the superintendent. As a result of the careful investigation it was often possible to find the cause of the failing and to put the man in some other department where his peculiar make-up would not conflict with that of the foreman of the department.

Referring to a remark by Mr. Rogers to the effect that one should "study to make them believe they are a part of us," he said it was an ideal expression of what the firm was trying to

do. While his own statement at the outset as to the financial end was a little more cold-blooded, in the end they were trying to make the men believe they were a part of them, and not only believe, but that they actually were a part of them. That was the whole thing. In order to encourage this attitude, records were kept. The speaker outlined a plan for paying a monthly or quarterly bonus, according to the average output of production per man, in addition to the extra earnings which a man would receive from his own individual increased production.

Mr. Baker further referred to the labor situation in Cincinnati more than a year ago, when a strike was declared in many of the plants in the downtown section of the city and where in the different plants the strike was more or less successful. Later, the attempt was made at Oakley and not over 30 or 40 men responded, and within a short time there were more men working than ever before. Without any suggestion or assistance from the management the responsible men in the shop got together and went over the whole situation and decided that it would be for their interest to combat the strike. An anti-strike committee was formed, which was most influential in averting the threatened labor troubles. Thus the men with whom these better relationships had been established fought for the firm when the occasion arose.

AN APPEAL FOR THE DURABLE SATISFACTIONS IN LIFE FOR WORKMEN AS WELL AS EMPLOYER

Richard A. Feiss, who came into the meeting as Mr. Baker was speaking about personal relationships in his organization, testified to the excellent spirit which he knew existed there, and which he said was as fine as in any plant in the country but one, and that one was his own.

While democracy was one of his hobbies, he felt that the durable satisfactions in life did not necessarily come as a result of any one scheme of organization or system. The tendency among business men and engineers was to think that when they had a good thing it was the only thing in the world. That was not true. If one analyzed Rogers' profit-sharing plan, or Gantt's method of paying bonuses, or Thompson's method of paying premiums, they would be found simply to be different methods for accomplishing the same thing, and their success would depend upon how they were worked out and what was the spirit back of them. In his own plant they were using a type of piece-rate system, by which he was sure that all of his 800 employees were as much partners as were Mr. Rogers.' The employees themselves did not pass upon the hiring of others, because he and they did not think they were competent to do so. An expert was employed to study the question and to pass upon them. He believed democracy which was subject to expert rule was the coming democracy and the one which America would have to adopt in order to become efficient.

He said that people work for two things: they work for money and they work for other satisfactions, such as contentment. If one thought they worked for money alone, let him try to get away his own employees: and if one thought they worked for the other thing, he might try to hire them without paying them.

The dollars-and-cents proposition must be looked after at first so that the workmen may procure those things which mean home and a decent standard of living,—and even a higher standard of living, because a man who stagnates is like a flower which grows no longer but fades, withers and dies. It must be realized that everybody, whether customer, worker or boss, must make progress and have an ever-increasing share of the things of the world; and then the important principles must be realized that the greater fruits of industry are only procurable by greater productivity and that greater productivity is only obtainable by mutual coöperation.

EFFICIENCY FOR THE MAN HIGHER UP

H. L. Gantt said that a lot of people had been talking efficiency and getting up fine charts, and when asked what they did with them they would say that they did nothing. We were all making charts to show how efficient the workman was, but very few were making charts to show how efficient the management was. There might be workmen doing something that did not need to be done at all, and doing it very efficiently. Until our efficiency system reached up to the executive and we could measure the efficiency of our executives with the same degree of accuracy that we now thought we were measuring the efficiency of the employees, it would not amount to very much.

Mr. Gantt referred to the Valuation Session to be held the next day and said that most of the valuation by accountants and financiers gave the valuation of bricks and mortar and machinery; but he had noticed in Mr. Polakov's paper to be presented, on Valuation of Industrial Properties vs. Valuation of Industrial Methods, that the value of machinery was not in the machinery itself but *in how it was used*,—in other words, in the human element behind it. Mr. Rogers had told about the little old plant that had gone to pieces and when he took it was not paying expenses; but by putting men and brains into it he got something out of it. How would public accountants have valued that plant before Mr. Rogers went there, and afterwards? They did not know how to do it and engineers must tell them how. Until we could measure and value the human element we would not be able to get anywhere in this work.

GENERAL DISCUSSION

By way of comment on the different systems of paying wages—premium, bonus, piece work, etc., W. S. Rogers raised the question of what was the distinction between a bonus and a tip. Were we tipping our men to do good work? At his plant the men were not paid on this basis for doing good work. They were partners. Every month they went to the bulletin board and read the comparison of sales as well as the comparison of their day's or month's work with the previous day or month. In response to an inquiry as [illegible] times, when he might have to lay off help, Mr. Rogers [illegible] that this had not been necessary. His [illegible] in times of business depression he ha[illegible]

W. O. Platt offered himself as [illegible] man who does not use charts." He [illegible] did not even have a time clock. T[illegible] a small business the question would [illegible] one must have in order to put in [illegible] Mr. Gantt's charts. He might be told that [illegible] age in efficiency by having [illegible] percentage by not using stop watches, no experts to analyze the motions of his men; and another percentage by having no time clocks. While he said he must admit that he was older than some who were present, and perhaps less active, he had found that every one of the devices or expedients mentioned took time and energy, and that unless this fact was considered the system would get top-heavy.

The point was made by A. R. Burnett that graphic charts such as had been mentioned as being prepared for the informa-

tion of the operatives should be used also to bring the executive closer to the details of the work. In reply, R. B. Wolf explained that he was using such charts to show the men what they were accomplishing and what was the progress of their work. This gave them the factor of interest and joy in their work, about which Mr. Feiss had spoken. He thought it was not necessary for the executive to be informed upon all the records contained in these charts, and a great many of them are not seen by the executive unless there is some particular thing for him to see.

The discussion was closed by David Myers, who said that he had dealt with one phase of efficiency, that which related to the factory power plant. He put forward a formula which seemed to him to sum up the whole situation very simply in two factors: the efficiency of any process was equal to the equipment modified by the human factor.

MACHINE SHOP SESSION, WEDNESDAY AFTERNOON

The Machine Shop Session was called to order by H. K. Hathaway, Chairman of the Sub-Committee on meetings for Machine Shop Practice, for the reading and discussion of two important papers on Standardization of Machine Tools, by Carl G. Barth, and A Proposed Plan for the Activity of the Machine Shop Practice Sub-Committee, by H. K. Hathaway. The audience was pleased to allow Mr. Barth an extension of the ten minutes' allotted time for the presentation of his paper. He gave his arguments with spirited energy and conviction, and illustrated his talk with lantern slides and deft sketches on the blackboard.

The object of Mr. Barth's paper was to enlist the coöperation of the Society in encouraging machine-tool builders to adopt certain standards for machine tools. He believed that a universal speed series should be used by all machine-tool builders for all machines such as lathes, boring mills, milling machines, drill presses, etc. His ideal of the generally accepted geometrical progression of speed is represented in the progression:

$$1 \quad 2^{\frac{1}{4}} \quad 2^{\frac{1}{2}} \quad 2^{\frac{3}{4}} \quad 2 \quad 2\cdot2^{\frac{1}{4}} \quad 2\cdot2^{\frac{1}{2}} \quad 2\cdot2^{\frac{3}{4}} \quad 4 \quad 4\cdot2^{\frac{1}{4}} \ \ldots\text{etc., or}$$

$$1 \ 1.1892 \ 1.4142 \ 1.6818 \ 2 \ 2.3784 \ 2.8284 \ 3.3636 \ 4 \ 4.7568\ldots\text{etc.}$$

His views on speeds hold also for feeds, except in the design of lathes in which the feeds for plain turning are obtained as a constant fraction of the screw-cutting feeds.

While the adoption of a standard speed series for all machine tools would be a step in the right direction, it would have to be accompanied by the adoption of a standardized amount of power.

For lathe centers, drill-press and milling-machine sockets, the speaker unqualifiedly recommended the universal adoption of Brown and Sharpe standards. He recommended the universal abandonment of the tang as a method of driving drills. The Barth key, with two sides beveled at 45 deg. and subject only to the crushing pressures, was adopted by himself some years ago as a drill drive.

Mr. Barth was extremely anxious that his paper be discussed freely by all present at the meeting, and the opportunity was taken by a few. William Kent's endeavors to learn why the Barth key was not supplied with beveled sides on both shank and socket sides resulted at last in a satisfactory answer after a keen competition at the blackboard and a threshing over of fundamental principles.

Adolph L. De Leeuw said that Mr. Barth had plainly showed how a good geometrical progression could be worked out and that it was an absolute necessity in all machine tools. Large boring mills, however, might be better without the geometrical progression as, when a large flywheel is turned, there is need for cutting at the rim and at the hub, but nowhere else, 90 per cent being cut at the rim and 10 per cent at the hub. Hence, the speeds should be bunched together to be correct for working at the rim and hub.

The time had come when the proper geometric speed series ought to be more closely studied. The attempt made by Mr. Barth to point out a geometrical progression which would be universally applicable deserved the highest praise. Personally, he believed that the progression as laid out by Mr. Barth was about as good as could be got under the conditions and with the knowledge we have at the present time.

The speaker regretted that there have been no investigations made on the art of cutting metals except for lathe work and for roughing cuts. Also, whereas everything possible has been done to study the matter of changing speeds on lathes, practically nothing had been done to provide for the necessary speeds and feeds on planers. The experiments on cutting angles had been carried on only through a small range. He said that he had personally made some little experiments with tools at an angle of not more than 25 deg. and found some very surprising results. He believed that if the Society as a whole would stand behind such efforts as Mr. Barth had spoken of, to standardize the range of feeds and speeds, much could be accomplished.

In an oral discussion, Harry V. Haight said that he agreed with Mr. Barth in the matter of belt feed. It had been his experience in the building of some two hundred lathes for munitions work that a 3-in. belt was sufficient to supply any demand for power and that any series of geometric progression of feeds could be obtained by changing pulleys. In contrast to this experience is that with expensive drill presses which were idle so much of the time because of broken gears.

MR. HATHAWAY OUTLINES HIS PLAN

Appointing Ralph E. Flanders to the chair, Mr. Hathaway took the floor for the presentation of his paper. Impressed with the fact that technical and scientific societies should be agencies through which constructive work leading to the development of a profession should be carried on, he proposed a definite plan of action for the Sub-Committee on Machine Shop Practice. He held that the sub-committee should classify the members of the Society with respect to the phases of machine-shop practice on which they were qualified to present papers, and should make a consistent effort to secure such papers.

A second and even larger undertaking would be the prosecution along predetermined lines of research that would result in definite advancement of the art. At present this is left almost entirely to the enterprise of individuals or companies, with no coördination of effort. Such work is now undertaken by committees of men whose time is so fully occupied by their own affairs that they can at best give an insufficient amount to the problem in hand. It would be better if the Society could employ experts who might give their entire time to investigation and research. A classification of machine shop practice had been worked out by the author and ap-

pended to the paper, arranged on the mnemonic system and so designed as to permit of easy expansion.

The interest in Mr. Hathaway's proposed plan was plainly evidenced by the discussion, written and oral, which followed its presentation. Mr. Flanders read three discussions, from Henry Hess, Robert C. H. Heck and R. J. S. Pigott. It is understood that the complete discussion will be published later.

Henry Hess pointed out that there are within the Society a number of committees which should concern themselves with the projects outlined in the Hathaway paper. The Committee on Technical Research is the logical agency to which investigation and experimentation should be entrusted, special sub-committees being appointed for definite tasks. A Research Committee is in existence but inactive, the Finance Committee having awarded it, unasked, "the munificent sum of $300" during the past year. The various Standards Committees sometimes concern themselves with certain phases involving research, but in too haphazard and uncorrelated a manner to secure the best work at the least cost. Special committees are occasionally appointed to deal with definite subjects, and could be aided by an adequate Research Committee.

Mr. Hess suggested a general supervising committee, not one that actually carried on research. It should originate or pass on projects for research brought to it, and advise the Council of the advisability of the Council's creating sub-committees, each to deal with a special line only. It would supervise the work of the sub-committees and the expenditure of the funds allotted to them, and strive to secure coöperation of other committees.

In closing, Mr. Hess said that it had been recognized by at least one engineering society that research of this character is quite within its functions, that it should be coöperative rather than left to individual effort, that it could be effectually carried on by such coöperation, and that effective aid and coöperation for the general benefit could be secured also from private interests that are quite ready to recognize that though their aid is to some extent altruistic, it is also directly beneficial from a personally selfish standpoint.

Prof. R. C. H. Heck made a plea for systematic information on cutting speeds, feeds, etc., not the extreme results of experiments that point the way to the future, but good routine average practice in up-to-date shops. This should be in the nature of handbook information, with due statement that practice is progressing and that quantitative values are subject to change. . . . What is wanted is, perhaps, a collection of well-selected examples rather than too definitely stated conclusions from such data.

R. J. S. Pigott, in full agreement with the attitude of Mr. Hathaway, stated that the principal difficulty in the way of getting adequate results accomplished is due to the utter lack of coördination between the various individuals and societies undertaking scientific investigation. One of the principal reasons for the comparative inefficiency of American manufacture is due to the attitude of secrecy which has all too frequently been taken.

Of the great mass of information on machine-shop practice available only a small amount has been collected by isolated investigators. A committee as outlined by Mr. Hathaway, having proper authority and a reliable system of effort, could do a great deal toward rendering this information useful to all engineers. The committee, to accomplish results, must be handled more like an operating company than a council of advisers. Mr. Pigott favored the Dewey rather than the mnemonic system of classification.

A. R. Shipley expressed himself as heartily in accord with the Hathaway paper. He dwelt upon the fact, brought out in the paper that engineers and men in charge devote too much time to the perfection of the design of their product and not enough time to the production of that product, a fact which is the cause of mismanagement in the machine shop.

Speaking of the small amount of literature dealing with machine shops to be found in the Society's publications, he said that more articles of a less technical nature are needed. Many papers given before the Society cover too large a field, and do not deal concretely enough with a specific subject. He believed that some such plan as outlined in the Hathaway paper would go a long way toward solving many of the difficulties which confront most manufacturers of machinery.

Henry J. Eberhardt suggested that the classification of data from technical journals, scientific transactions, foreign publications, etc., should not extend back further than one year at the outset, in order to determine how valuable further research into the past would be. He foresaw a possible danger in starting a large museum of ancient practice.

A much better method of using the committee would be to coöperate intimately with the Research Committee and to suggest to the commanding officers of U. S. Arsenals, Navy Yards, and others in Government service, and to the students in post-graduate technical work, the use of mechanical equipment in those various institutions for definite research work and tests. He cited the case of an inventor interested in the use of aluminum rather than bronze bearings for a steel shaft, and the impossibility of finding proper authoritative data. Tests made by the inventor himself would be narrow in their scope, but a well-planned test, using different diameters and a wider range of materials, might lead to practical discoveries.

The great opportunity for the Committee would be to bring before our members each year the best results of the past year's experience in typical shops. It was his hope that some such plan might be in full operation very soon.

"I wish to give this paper my hearty commendation and hope that Mr. Hathaway will keep on with the good work," said William Kent in opening the oral discussion. Mr. Kent believed that the machine-shop branch of the mechanical engineering profession had been given too little attention. The work to be done by the proposed Committee was to ask questions. Ten thousand questions might be asked of the men in the different shops, but it would first be necessary to have a secretary and a card index. Then, with questions asked and distributed around, it would be possible, perhaps, to have ten answered per year.

Mr. Kent favored the mnemonic system, which allowed 8000 combinations of three symbols, whereas there were only 999 possible with the Dewey system.

John J. Ralph thought few people knew how to buy machine tools. The prejudices of the buyer and the persuasiveness of the seller entered too greatly into the purchase. Nowhere was there a list of the basic facts which should be considered before a tool is bought. The various types of machine tools are not even known in the average shop. Catalogs and trade-paper advertisements constitute the principal source of information. There should be a standard method of testing machine tools for accuracy. There being specifications for the test and acceptance of boilers, why not for machine tools?

Elmer H. Neff suggested that The Journal devote a page per month to questions on machine-shop practice which required answers. He was certain that the results of experiences sent in response to the questions would bring the desired information.

Wm. T. Magruder commended the paper and said that the Gas Power Committee sometime ago had attempted similar work, but without results. The colleges would be glad to cooperate with the manufacturers if the latter would come to the colleges with their problems. If the problems were larger than could be undertaken by a single institution, they would be solved piecemeal by several of the colleges working together.

Other discussion of a commendatory character was offered by Chas. J. Simeon, Carl G. Barth, and others.

In closing, Mr. Hathaway explained that he could not then answer the points brought out in the discussion, but that his formal closure would appear later in the Transactions. He did suggest that the Committee must distinguish between questions of design and machine-shop practice. It should confine itself to questions of practice.

FIRST VALUATION SESSION, THURSDAY MORNING

THE First Valuation Session of the Annual Meeting was held on Thursday morning in the Auditorium, Vice-President Henry Hess acting as Chairman. Three papers were presented for consideration and, since all of them dealt with the same general subject, were read in succession before the discussion was opened, the first two by their authors and the last by the Secretary, in the absence of the author. The first paper was by J. G. Morse, entitled Accurate Appraisals by Short Methods, in which the author described the method of appraisal developed by the Associated Factory Mutual Fire Insurance Companies, which combines approximation with theory, and is much shorter than one necessitating a complete and elaborate detail. The second paper, by Prof. John H. Gray, was entitled How Does Industrial Valuation Differ from Public-Utility Valuation? and dealt with the valuation problems growing out of governmental attempts to regulate the various public-service industries. The final paper, The Relation Between Perpetual-Inventory Value and Appraisal Value, by Charles Piez, emphasized the necessity for determining proper rates of depreciation in order to establish true costs of products.

MR. GANTT OPENS THE DISCUSSION

H. L. Gantt, being called on to open the discussion, said that things had so changed in the world in the last two years that a great deal that Professor Gray said, he thought, was a little out of date. It might be good law, constitutional, and proper, according to our viewpoint of a few years ago, but we were thinking in different terms today. The war had taught Europe something. England had just made a change and put Lloyd George at the head of the Government. They had brushed aside the powers that had controlled, and had put the power in the hands of the man they believed most capable of "delivering the goods." Our laws and our regulations would have to be so adjusted as to produce the greatest possible values for the community. England, to save her life, had been obliged to do that.

We were in a class with England, and had not learned from the war as England had. If we were ever confronted with the same problem that England was, our salvation would come through the men who knew how to do things, and a solution of our problems would be in the hands of our engineers rather than our financiers.

Professor Gray's paper related to a condition of affairs when the financier was the supreme power in the world. Today the engineer was successfully disputing that power with him in the warring countries.

No theory of valuation would be complete in the future unless it took account of the value of the engineer, and Professor Gray had left this entirely out of his calculation.

A. E. Flowers asked for a definition of the term "reducing balance" employed in the table of depreciation rates in Mr. Piez's paper.

In the absence of the author, Carl G. Barth explained the term, stating that if a machine was worth $1,000 today, and it was depreciated 10 per cent on the reducing balance, it merely meant $100 for the first year, and 10 per cent for the second year, and that left 90, and the amount would never be entirely extinguished. If a machine depreciated 10 per cent a year, however, its value would be wiped out in ten years.

Speaking to the papers, he was convinced there had not been a single improvement made on the accounting and cost system that Mr. Taylor invented twelve or fourteen years ago. Mr. Taylor had started out with the idea that the simplest way of proceeding was to get a cost that was such that the difference between selling price and cost price was absolute profit. There was no question about that being the correct point of view. He wanted nothing to go into the cost except the things that had been expended or lost in carrying on the business.

Regarding Professor Gray's paper, Charles Whiting Baker thought it incorrect to state that the reason for establishing public regulation of utilities had been to stop speculation. It had been the shippers, the travelers, the people who bought gas and electricity, who rode in the railway trains and cars, who were behind the great movement that demanded public utilities should be regulated, rather than innocent purchasers of worthless securities. He was unable to understand why Professor Gray did not accept the cost-of-production theory of valuation, as it seemed to him to lie at the base of our whole work of valuation. In all our valuation work it was necessary to go back to this theory. Suppose a manufacturing concern were to issue a balance sheet showing what its property was worth, based on its earning power. Now, its earning power would vary from year to year, and every competent appraiser knew that the only safe way to value an industrial property or a manufacturing property was to value it at what it would cost to replace the buildings, put the machinery back there, and duplicate the plant as it originally stood. Why? Because in the nature of the case some other competitor might come along the next day and duplicate the property and go into the business; so the only safe way for a fair valuation was to base it on the cost of reproduction.

DEFINITIONS DEALING WITH DEPRECIATION

In a written discussion of Mr. Morse's paper, Harry Barker[1] contrasted the high and burdensome costs of public-utility appraisals with the moderate figures resulting from the use of the author's method. In his opinion, the pioneer utility appraisers had felt impelled to present an impressive array of evidence and to substitute for experience and ac-

[1] Associate Editor, Engineering News, 10th Ave. and 36th St., New York.

cumulated data a logical system of scrutinizing property details. The older commissions, however, should have accumulated by this time sufficient data to be able to adopt the author's methods if that were deemed desirable. It would be helpful to learn how the author would apply his methods in cases in the utility field where the effect of seeking out original conditions of construction might change the valuation result by 100 per cent or more over figures based on present conditions as superficially indicated.

Turning to Mr. Piez's paper, Mr. Barker said that the fundamental term "depreciation" had become so involved in a maze of differing definitions, that even when engineers endeavored to use it quite technically it conveyed different ideas to different persons. In an attempt to harmonize some of these differences he had been led to study the various meanings attaching to the term, and had found that it was possible to clear up matters by employing six definitions, having different shades of meaning, which definitions he appended.

In a written discussion commenting on the possible value of a valuation, L. K. Frank[1] said that it was not improbable that industrial property might be subject to public regulation of return on investment before the close of the century. The Federal Trade Commission was advocating the adoption of accounting methods by the manufacturers of the country, which in many instances would call for valuation work, and upon the care and industrial statesmanship of the engineers involved would depend the future course of this movement for social control of industry. Social progress was inevitable, and it was open to the engineers to play a part in this movement, the importance of which could scarcely be measured.

The Chairman called on Dean M. E. Cooley, who, among other things, said that he felt a degree of responsibility concerning the use of the word "depreciation" in connection with appraisals. It came up in connection with the appraisal of the Michigan railroad properties in 1900, and had come to play a very important part in the decisions of the various State Commissions since organized; a most unfortunate part, he might add, for it was not entitled to have the use that had been given it, and should be discarded in certain classes of investigations. For example, there was now in process of solution a valuation problem of a very large utility property not far from New York, which involved the depreciated value of the property as observed. It was a complex electric light and railroad property, involving many plants, old and modern. In the old plants the machinery was about ready to be discarded, and the machinery of the new plants substituted. The question was as to the value of the machinery to be discarded. It had perhaps been valued by observation, being 20 or 25 years old, at, say, $180,000, and the question raised had been whether that was a fair value. So an investigation had been made to determine its present real or commercial value, comparing it, in an economic way, with the machinery of a new plant. Considering the distance between the two plants, the necessity for constructing transmission lines, and the necessity for wiping out in a sinking fund or otherwise whatever value there might be in the old plant, the commercial value of the old plant today, instead of being $180,000, was about $360,000!

DEPRECIATION NOT INVOLVED IN RATE CASES

The word "depreciation" had no place whatever in the investigation of a rate case. For example, a railroad was made up of a vast number of elements, all new in the beginning and each having, say, 100 per cent value. After a few years the elements—ties, rails, locomotives, cars—wore in various degrees, and were replaced by new elements. After, say, twenty-five years this property would come to a stable condition and would continue to exist in perpetuity in a condition less than 100 per cent for each of the elements, but in a condition which might be expressed, say, by 80 or 85 per cent. It could be demonstrated very conclusively that to attempt to maintain such a complex property at a higher percentage than what we call its normal percentage would be a waste of money, because elements would have to be thrown away or discarded before they were worn out. Also, if the property were maintained at a very much lower percentage it would be equally a waste of money, because the property itself would be endangered and the business which it could do would be diminished. The property could, in this 80 or 85 per cent condition of efficiency, render the maximum service which it was capable of rendering. To obtain it in a normal condition, expressed by 80 or 85 per cent, we had had to expend 100 per cent. Therefore, that was the investment, and it could not be had for anything else. If there was 100 per cent investment in that property standing at 80 or 85 per cent condition, as we value it, there being, say 15 or 20 per cent depreciation, then we should allow in a rate-making case 100 per cent, and depreciation would have no purpose whatever in the problem.

The word "depreciation," however, did have value in other cases, and it might have value in a rate-making case where, for instance, the financial policy of the company had involved the laying aside of money which the English would call a "sinking fund" to back up the difference between the 100 per cent and the 80 or 85 per cent. If the earnings had already been sufficient to enable that to be done, then perhaps we should take the 80 or 85 per cent for the rate-making purposes rather than the 100 per cent, but in America we took our sinking fund in the form of dividends.

THE PRODUCTIVE LIFE OF A PLANT

L. S. Randolph stated that he had had a great deal of difficulty with the word "depreciation," and in figuring out such questions attacked the problem in the beginning by assuming that a piece of machinery or plant could be so repaired or renewed as to do the work as well as when first erected. After that it was a question, first, of using the word "obsolescence," and then the term "productive life," or, in other words, what would be the productive life of a plant, and that, he thought, would have to be laid aside to return the value of the original investment of the plant when the productive life had ceased. He had come across some cases—in agriculture—where apparently the productive life was infinite, and where there was actually appreciation of value. Sometimes legal enactments would abruptly cut off the productive life of a plant.

Engineers, Morris Knowles thought, should be very much interested in such a paper as Mr. Morse's, because the fact was obvious that appraisements were costing enormous sums of money. There was much unnecessary refinement, and in the end the people, the rate payers, were paying for these things. In Pennsylvania all matters of fact were referred to an Engineering Board consisting of one engineer appointed by each side and the chief engineer of the Commission sitting as chairman. Engineers when they faced each other across a table understood whether each one knew what he was talking about, and they did not have to count all the bolts and nuts and gaskets which were used in a steam pipe to determine that a certain number of boilers cost so much money. They could

[1] 15 Dey Street, New York.

persuade each other, and it was different from trying to persuade an attorney or the Court.

He would like to differ from Professor Gray in one respect, and that was that valuation in amount necessarily depended on the purpose. The report of the recent case of the Los Angeles electric situation went into that thoroughly, and showed if you could affect the rate as to value for rate-making purposes, this value should be used for other purposes. Certainly in the case of a purchaser the value would control, because he would not want to pay any more for the property than what he thought he might get out of it if it were subjected to regulation.

Referring to Dean Cooley's remarks about depreciation, he thought that if a depreciation fund was in existence, then the property was entitled to earn on 100 per cent; but if the utility had not that fund on hand, but had pocketed it, it would not be carrying out its trusteeship to the people, and therefore depreciation should be deducted.

In regard to the question of valuation on the basis of cost of reproduction of a plant, William Kent stated that there were some cases where he thought it might not apply very well. For example, what had been the valuation of the power plant of the Interborough Rapid Transit Company two years ago, when it had been equipped with magnificent alternating-current generators driven by engines of the very highest type known, and these engines were as good as new, for all practical purposes, and had cost $1,000,000, or twice that, probably? On the cost of reproduction you would say that you would value that plant on the basis of those engines in use, but if the owners of the plant had decided that these same engines, good as they were, were using more steam than more modern engines or turbines would use, and it had been necessary to throw them out and put them in the scrap heap, and spend two millions of dollars to replace them by turbines, then what was the valuation of the plant before the contract for turbines was made? It certainly was not the cost of reproducing the plant going into the scrap heap. Some allowance for valuation would have to be made on the reproduction basis.

It seemed to him that we had not arrived at any proper theory of valuation because we had no leaders of thought on this subject who represented the public. We had had court decisions by judges who were not experts, but who did the best they could with the limited light they had, but no authoritative statements by leading lights representing the public at large, and that was what we were looking for. He thought we could get such a statement some day from engineers rather than from lawyers. It was a question of strong common sense rather than of the traditions of law. What was needed was a few strong and intelligent students of the matter who would put their ideas together and get the question solved on the basis of exact justice between all the parties concerned, especially justice to the community that paid the bills.

TWO KINDS OF OBSOLESCENCE

Oberlin Smith said that his rule was that things were worth what it would cost to reproduce them tomorrow if they were burned today in their present condition. With a plant all new, it would mean the cost of a new plant. That might be more, or less, than what the plant and its contents had cost. They might have appreciated or depreciated since they were new. On everything new it was necessary to find the percentage of obsolescence and take off that percentage, but in a machine shop it did not pay to have that value too low, as the tools were not efficient unless they were kept up, as Dean Cooley said, to 80 or 85 per cent efficiency, so that they did work, and to rate them at that was evidently fair. The principle of obsolescence might put them down to nothing.

There were two kinds of obsolescence. One kind would be the tool not being up to date, and we could apply that theory to a certain extent, so if it were likely that the tools would have to be altered or repaired, that should be taken into account in the valuation. The other kind of obsolescence was the change in the demand for the product. Certain things would be in fashion at one season, and then become obsolete, and the tools for making them, although as good as ever and in absolutely first-class condition for performing their functions efficiently, would be of no use for their special purpose; and so we had to take into consideration, and be on the lookout constantly for, the obsolescence of tools which in themselves were up-to-date and efficient, but for which there was no employment.

Some people depreciated a set of machine tools ten per cent each year, and that soon made them worth one-half or one-quarter of their original value, when they were as good as ever. His rule had been to allow a certain small amount for depreciation each year and keep the tools in good order. If a tool was run down and needed repairs, or an additional part was applied to it, then it was worth more at the end of the year when repaired, and perhaps 50 per cent of the original value spent on it, and it was not right to keep depreciating it right along. It was worth as much as when new, and under this method of allowing for depreciation we kept the inventory jumping up and down.

The public utilities were an entirely different matter—they were things which had a value outside of the actual plant value. The plant value of a concern might be 80 per cent of its original cost, say, or anywhere up to 100 per cent, and the concern might be sold out at a 200 per cent valuation because of surplus which had accumulated by extra profits, unpaid dividends, etc., so that the commercial value of the plant should not be taken as the actual value, the mechanical value of the plant, because the plant itself could be reproduced for the 100 per cent, and all this extra was in the form of good-will. If a plant sold out for 200 per cent of the cost, it would be because of earning power, and earning power had to be taken into account when we valued the plant for the market for selling it, or perhaps for taxing it. We should consider that a plant was not necessarily more valuable because of its great earning power, for that earning-power increment belonged in what he termed "good-will" or anything we would like to call it.

DEPRECIATION PURELY AN ITEM OF OPERATING COST

Accountants and engineers, thought W. L. Whittlesey,[1] should have the same point of view of operating facts, and an accountant might be excused for saying that depreciation was an item in operating cost, for it was not anything else. If depreciation meant anything it was an item of operating cost and nothing else. The idea of a public-utility corporation was that it should do two things: it should enlist and develop ability within its ranks, and it should give service to its patrons. In the future the problem of regulation might be taken up in that way, but the trouble was, of course, that the lawyers took it up as a matter of property, and so there were such expensive valuations as that of the New York Telephone Company, costing $3.00 per thousand of value; but the idea

---

[1] 15 Dey St., New York.

there had been to do a thorough engineering job, to head off any inquiries of this sort, and to put an end to a situation that had been dragging along for about ten years. Another valuation fact lay in the change in the price of copper; this, every one knew, had tripled within the last year or two. A few years ago corporations had had a base figure of 16 or 17 cents per lb., and talked about writing down the fixed value of assets which depended on the price of copper, as the valuation was too high, and now the valuation was about half the market price!

Oberlin Smith thought that the best way to thresh the matter out would be for the Society to appoint a committee, perhaps a permanent one, on valuation, and work in consonance with other societies. In his opinion there should be a distinction between the mechanical value of a plant and the commercial value, the increment being placed on franchises and the earning power and various things of that nature. This was not a time to make valuations, because the whole country and the whole world were in an abnormal state, and no present valuations would be indicative of what they might be after the war was over.

Referring to the paper of Mr. Piez, in which he presented a schedule of depreciation in rates, John L. Harper said that financiers often asked their engineers to present to them certain factors for determining the amounts to be written off each year, depending on the conditions existent at the time, and it was along that line he wished to inquire of the author as to his method of determining these factors in relation to the salvage values, and the fluctuations in actual values of the materials covered in the several items.

Edward W. Bemis,[1] in a written communication dealing with Mr. Morse's paper, stated that in his opinion, unless both sides agreed, the side not giving a detailed appraisal would be at a disadvantage; and that only great reputation on the part of the appraisal company would enable a short-cut appraisal to stand up against a detailed one. Unfortunately, most of the appraisal companies of large reputation had applied such high overhead charges and so strongly endorsed going value as to be looked on with distrust by cities. Personally, he believed that where both sides exhibited a coöperative spirit, short methods could be employed which would yield justice to all concerned.

DETERMINING THE VALUE OF A PLANT

In a written discussion of Mr. Morse's paper, Chas. T. Main said that for the purpose of purchase or sale, for condemnation, or for establishing a fair cost value for accounting purposes, it was unnecessary to make elaborate schedules of all the items in a plant; oftentimes a rough approximate value per unit, such as a spinning spindle, was near enough, if the plant was what could be termed standard.

The first step in determining the value of a plant was to ascertain its replacement cost, and then to compare this with the cost of a new plant constructed on modern principles, the output of which would be equal in amount to, and of as good quality as, that of the existing mill. A comparison should then be made of the cost of running the two mills, and if the organization of the existing mill could be so changed as to make it as efficient as a modern plant, the cost of such change would be deducted from the replacement cost. If it could not be changed, the greater annual operating expense would have to be capitalized to some reasonable per cent and the capitalized sum deducted from the value new.

[1] City Hall Square Building, Chicago, Ill.

After thus determining the value of the plant, if new, account had to be taken of depreciation. To be safe in accounting, it was necessary to mark off each year an amount that would fully cover all possible decrease in values from age, wear and tear, and obsolescence; but if this were carried too far the value on the books would become less than the true value, therefore revaluations should be made at stated periods, say every five years, at which time the write-off for obsolescence for that period, at least, might be readjusted and corrections made for decided changes up or down in replacement values and for any extraordinary repairs or renewals.

In a general way he had found that the useful life of the common types of machinery that had been run about ten hours a day, had received the usual good care, and had not been superseded by machines that would render them unprofitable to run, was about 30 years for cotton machinery and 50 years for woolen and worsted machinery. Well-designed and substantially built mills, when properly kept up, should be good for 100 years.

In appraising a property in operation, there should be added to the physical value the "going concern value," or the amount required to get it started so that goods could be marketed. This amount was made up of (1) interest during construction; (2) engineering expense; (3) interest, depreciation, taxes, and insurance for the period required to start up the mill and get the goods on the market; (4) cost of starting up; and (5) allowance for wastage and damage to product. He had found that for the sum of the first three items it was safe to take 10 per cent of the replacement cost, and for the remaining items, 5 per cent, or a total of 15 per cent.

Chas. W. McKay,[1] in a written communication discussing Mr. Morse's paper, outlined a method of manufacturing-plant appraisement patterned after current practice in public-utility valuation work. He also said that, while the author's plan of appraisal by short methods might satisfy his clients, or his employers, who had sufficient confidence in his judgment and knew full well that he would be able to substantiate his valuation in the event of a call for claim adjustments, nevertheless it was quite probable that insurance organizations would be somewhat loth to accept valuations made by outside engineers and based upon the author's rather broad-gage methods. And it was probable that an engineer in submitting a short-method appraisal would experience considerable difficulty in getting the court to accept it in the event of a law suit over the value of a manufacturing property or in using it as a basis for capitalization. He thought that the auxiliary building equipment, such as elevators, piping and wiring, should, so far as possible, be considered a part of the building rather than as a part of the machine equipment. While some of the appraisals prepared by the so-called appraisal companies contained needless detail, the short-cut methods of Mr. Morse, on the other hand, seemed to him to be a little too approximate in their nature to warrant their general adoption for engineering valuations. Probably there was a happy medium between the two plans, which could best be reached by observing, and to a certain extent copying, the methods adopted in the public-utility appraisement field.

COMPROMISE WITH UNWARNED INVESTORS NECESSARY

In a written discussion of Professor Gray's paper, Robert L. Hale said that, unfortunately, people had been permitted to invest in public-utility companies with the expectation of get-

[1] With McMeen and Miller, Engineers, 1454 Monadnock Block, Chicago.

[illegible] ry to induce investment. As a [illegible] to permit these unwarned investors [illegible] in the enjoyment of the returns for which [illegible] did not prevent us from adopting a [illegible] warning [illegible] investors as to just how much they would be permitted to earn, and of preventing the value of [illegible] from becoming more swollen than it now was. He desired to emphasize the fact that the problems dealing with warned and unwarned investors were entirely dissimilar and should be treated separately.

In regard to past investors he thought some form of partially unsatisfactory compromise necessary. If the courts meant that they were entitled to a fair return on the exchange value of the entire business, then no reduction in net earnings was permissible. But if they meant to permit a fair return on the exchange value of the "property," and meant to distinguish the value of the property from that of the entire business, then the cost of replacing the physical property with an equally efficient substitute would throw light in some cases on the value of the property as distinguished from that of the entire business.

When it had been decided how much return should be permitted to any public utility, there was no reason why anything more than that return should go to it for accidental reasons. It therefore seemed best to permit a rate which would be pretty certain to result in a return as great as that which had been decided on as permissible, and then to hold the company responsible to the public for all the excess above that return, either by paying it back into the public treasury, or by putting it back into the plant without adding to the amount on which it should earn a return in the future.

Discussing the paper by Mr. Piez in a written communication, Robert J. Hearne said that the subjects of inventory, cost, and valuation were so interwoven that they should be treated together. Too many valuations, he thought, were colored by future prospects. On the other hand, one could not ignore present conditions. While abnormally good now, a new basis for valuation would arise with a change in times. Valuation had to be recent to be of any good.

In actual practice, extending over many years, he had found it practical and necessary for the purpose of inventory to make (1) an estimate of actual cost, (2) a conservative valuation for his own guidance, and (3) a valuation for insurance purposes. He thought that the work attempted by appraisal companies should be done by one's own employees. At the best, outsiders could only deal in figures, not facts; they could not possibly know the business itself. They did have a value, however, in detecting fraud and incompetence.

Properly kept, a perpetual inventory was a time saver and a daily corrector of values and costs, and kept everything up to date. It took some trouble to install and some thought to keep going, but it paid. He had had over 15 years' experience with a method that was adapted to almost any business, that saved time, trouble and expense and that could be applied to a new business very easily and to an old one a little at a time. The discussor then described in detail the method mentioned.

AUTHORS' CLOSURES

J. G. Morse, in closing the discussion on his paper, said that the fact that there were so many different opinions in regard to depreciation, and what should be considered depreciation, made it all the more unnecessary to go into detail. As to the cost of his appraisals, he thought the range was from 15 to 25 cents per $1000. He had been asked to outline his procedure in the case of an industrial property. He understood that in Vermont, in appraising the telephone company, they measured the length of every pole and put a different price on each pole where it varied six inches in height. He would have taken an average price per pole, and ascertained the number of poles to the mile and the number of miles of line the company owned, and obtained the value by using that factor. He would have averaged the poles and wires in that way. In the case of a railway valuation, he would take the track at so much per mile; he would take the trestles according to their construction and classify them into different types, at so many dollars per lineal foot. In short, he would go over the property, naming a unit factor on every part of the property and apply it; going into detail in each individual case for one sample only.

Prof. John H. Gray, in closing the discussion on his paper, began by saying that anyone who thought that railway capitalization did not affect rates, should recall the traction history in New York and Chicago between 1899 and 1907. The things that started the movement toward regulation were, first, fluctuation in rates, and second, the enormous fortunes made by speculators. They were the red rags that stirred up the agitation.

As to the cost-of-reproduction theory, he did not accept it, first, except as it served to put the value up with the social growth, and therefore to give the benefit of the unregulated industries to the people who were fortunate enough to have bet satisfactorily upon the rapidity of the social growth, because it was absolutely inconsistent with any regulation at all. In the second place, he did not accept it because, if he understood the development of human society, in the long run it would conform, not to the precedents of the law, as someone had said, but to the necessities of economic and social life. The cost of reproduction arrived at something that anybody who understood the situation and was dishonest wanted to find. In the next place, it was primarily a subject of cost, and if our social system was to be organized on the basis of cost and mere speculation, we would go to the bow-wows, and we had better get down to the facts. He was opposed to the cost of reproduction because no one wanted to reproduce one of these important properties. In the next place, there was no human experience on which to base an intelligent estimate as to how long it would take to reproduce the property, or how much it would cost.

We all agreed that the public utilities were necessary for the maintenance of our civilization on its present basis. The company wanted its monopoly guaranteed, and wanted its monopoly profits. In the final analysis we had got to have the industries carried on, and if we allowed private capital to do it, we should have to allow a rate of income that in the long run would induce men to put in capital enough to meet the requirements of these enterprises and to meet the needs of the growth of a progressive state of society. It had nothing whatever to do with value. It had to do with the contribution of money and service, and service could not be measured in money. The State did not allow them to discontinue service. When land went up in price they were not allowed to sell the land. The land was dedicated to that particular purpose, and in many utilities it had been acquired by the company with a limitation for a particular purpose, and not by the exercise of eminent domain, which was a controlling element.

In reply to a question by Clarence H. Tolman in regard to the capitalization of losses, Professor Gray said that if we were going to hold the company down on the present law to what was called a fair rate, both the custom and the tendency

were to make that rate uniform. The tendency, therefore, was to hold the company down in prosperous times to the average rate. In lean years, though, there would be losses. That being the case, he would say that the public had got to guarantee the losses, provided they were not vicious, fraudulent, or grossly reckless, for if they were not compensated for in some way, capital would cease to come in and the service would suffer. The viciousness of the cost-of-reproduction proposition, and the viciousness of all intangible propositions, was not that the man ought not to have some compensation, but in the method of giving it. That was what was wrong, and this method of cost of reproduction, in his judgment, had been the reason for one of the most powerful movements toward public ownership, and he assumed his hearers knew that the traditions of the organization of our Government were wholly inadequate and too antiquated to manage business effectively; but he thought these losses should be set up in an amortization account, and should have a temporary larger rate of income, but should not be permitted to disturb the capitalization.

SECOND VALUATION SESSION, THURSDAY AFTERNOON

The Second Valuation Session was likewise held in the Auditorium, and was called to order by Chairman Hess, at 2:15 p. m. Two papers were offered: the first, by Walter N. Polakov, entitled Valuation of Industrial Properties vs. Valuation of Industrial Methods; and the second, by H. L. Gantt, on Productive Capacity a Measure of Value of an Industrial Property. The procedure of the morning session was followed, both papers being presented before discussion was begun.

In his opening remarks, made in lieu of a formal presentation of his paper, Mr. Polakov referred to the Chinese custom of the bridegroom paying for the bride, in accordance with her worth, a ransom to her parents. That ancient practice, it seemed to him, prevailed in our day when we put the value of the plant in accordance with the equipment of these plants, and neglected to consider what the plant was capable of doing for society. The modern financier seemed to have difficulty in getting rid of the habit. The other day his opinion had been asked as to how much more equipment a certain mill would require in order that appropriation might be made for it. It was desired to increase the output from 13 tons a day to 40 tons a day, and an actual test had proved that they had the capacity to produce from 60 to 80 tons a day, but for some reason or other they had not done it. That was evidently due to a lack of method. How we were to appreciate or appraise this method, and the methods in vogue, seemed to be a question which should be answered before we went into the question of how much of the equipment was necessary, and what part of it we knew how to use, and what part of it we did not care to use, for some reason or another. The substance of the matter was that people had not yet realized the fact that those who did not know how to run a business for the benefit of the industry should be denied the privilege of running it at all.

Cases were known of important railways that employed their extensive equipment but 20 per cent of the time, leaving it idle 80 per cent of the time on account of poor planning. Certain electric railways, for some reason or other, had preferred to keep their power plants and equipment idle two-thirds of their capacity and buy power from outside sources for double the price that they could develop it for themselves. Yet this idle equipment was, in fact, not an asset, but a liability to society. Some one had to pay for it—the consumer—and in his judgment it was the duty of the engineer to reverse this condition of affairs as much as he could.

MR. GANTT'S INTRODUCTORY DISCUSSION

Mr. Gantt, on being introduced, began by saying that inasmuch as the value of an industrial plant was measured by its ability to produce values, such a plant, which was not operated, had not actual but only potential value, and actual value was conferred upon it only when human intelligence and industry were added to it to produce the results for which it had been created. The fact that industrial plants were created in order to make some article which could be sold at profit, or to render some service which could be sold at profit, amply justified the statement that their value was dependent upon how they performed their functions. One might therefore divide the value of a going industrial property into two classes—that of the potential or static value of the plant itself, and that of the dynamic value of the organization operating it. In the past, the former had been given attention by accountants, almost to the entire exclusion of the latter, in spite of the fact that the stock-market prices and sales values of plants actually, though indirectly, reflected both values combined. If we would get a clear conception of a going plant, we would have to find the means of measuring the value of the operating organization, which had often far more to do with its successful operation than the particular constructions and equipments of which it was composed.

In the operation of an industrial property, it was seldom that all the expense incurred during any one month could be utilized to advantage; but if we could find how much was utilized and how well it was utilized, we could get some idea of the efficiency of the management. How well the money used was used, was indicated by the cost of the article produced; but there had, in general, been no indication as to what became of expense incurred but not utilized. How much expense was incurred but not utilized, and why it was not utilized, were vital factors in any attempt to measure the efficiency of the management: hence it was to these questions that we gave special attention in this paper.

At the Buffalo meeting last year, he had read a paper on the relation between production and cost, wherein he had contended that the true cost should include only those items needed to produce the article, and that any other money expended while these articles were being produced for any cause whatever should be charged to some other account. People were pretty generally keeping an account of the money expended for producing articles, but in few cases were they taking care to find out how much money was expended that did not produce anything.

We were all familiar with the fact that idle machinery cost money, even when it was idle. Interest on the money invested, taxes, depreciation, insurance, etc., all went on whether the machinery was used or not. The value of a plant was very materially influenced by the amount of the above items that were unused or unusable.

This was a factor which was directly in the control of the management, and did not in any way concern the inefficiency of the workman, but it was a real factor in the valuation of

a plant. Hence, a chart of the nature shown in his paper was of great help in determining the value of the going plant.

Referring to Mr. Gantt's chart, W. S. Rogers thought if it were real it would show the unbalanced condition of the plant. That was just as important as anything. The divisions could be carried out further, and show plainly and clearly inefficiency, and the chart would point to and almost name the man, up in the higher office, who was killing himself at his desk, absolutely unable to go out and get a meal, almost, and the biggest leak in the plant, knowing the least about it.

AN INSTANCE OF THE EFFECTIVENESS OF CHARTS

Carl G. Barth said that he wanted to bring up the question of the human element. He did not think there was a better way to treat a man than to give him a good machine to work with, and that was the reason he started in first with the machine. He was not so enthusiastic over making time studies on all routine operations, and had been with four companies without taking a single time study on the Taylor system.

Charts like the one shown had been made under cover, but they had not been presented before the Society heretofore, and he was thankful to Mr. Gantt for having done it. A similar chart was now being carried out with a great deal of detail at the Winchester Arms Company, and it showed the various items by lines instead of percentages, which in his opinion was far more effective. He had been with a certain company and they had increased the production 2.5 per cent. He had then sent in a report to the president that they were then using, with the increased percentage, a little over one-half of the equipment of the company. Mr. Taylor had done the same thing.

In regard to machine idleness, William W. Crosby stated that it was known among textile mills that parts of looms for a whole year at a time were in the storehouse. They had tackle and slings, and looms were put into operation at certain times because certain grades of cloths were demanded, but at other times they were not required. With a sufficiently world-wide market we could keep our mills running at somewhere near the capacity for which they were designed, but you could not run mills fully and economically unless you had the orders to run them on.

HOW PROFITS SHOULD BE FIGURED

H. B. Cheney[1] was of the opinion that every mill had some factor which, running on a particular product, was the controlling factor. For instance, in Mr. Gantt's cotton mill it was probably the looms. You could not make any more goods in that mill than the looms could turn out. Consequently, when it came to making a chart, such as Mr. Gantt had, the idleness portion of the chart should show, as he had arranged it, upon the 100 per cent method; but when you came to the factors or rates upon which you were making your calculations of cost, that policy should not be longer continued. You should take the controlling factor of your mill, your looms, your spindles, whatever it was that controlled the product of the day, and say that all the other departments which were necessary to supply those looms were supply departments, and if your looms ran 100 per cent, that 100 per cent of all the expense of having that department supplied should be consumed in your cost; but if your looms, which were the controlling factor, only ran 85 per cent, then only 85 per cent of all the rest of the overhead should be consumed. All the departments having a chart on a 100 per cent method would show you just the things Mr. Rogers had referred to. It did unquestionably bring out with the greatest clearness every point that was out of balance for that time. But it might be an entirely different matter six months later.

Heretofore it had been the custom to figure profits upon a percentage made upon the article sold. He did not believe it was the right basis to proceed on. What was the most profit that could be made out of a given plant? It was not necessarily that made by manufacturing the article which showed the largest percentage of profit upon its cost, but that which showed the largest profit for the machines run. Therefore, profits, instead of being figured on the article made, should be figured upon the running of the machines. In other words, one article might earn $1.00 a day profit on a loom, and another one $5.00 a day, and the article which earned $1.00 a day might make 50 per cent profit and the one which earned $5.00 a day but 10 per cent profit.

As to the human element, there was one factor in connection with that which he wished to bring out, which was that heretofore men had usually been hired without any particular reference to the efficiency of the individual for the work which they were intended to do. You could not take a man without any regard to his adaptability to it, and force him into a certain mold from the beginning to the end, training him without finding out, when he came to that point, whether he was the best man that could be trained for that particular purpose, and expect to get satisfactory results. He believed it was possible, and would be possible, to apply gages and tests for the purpose of determining the efficiency of the unit before putting it in use.

As to Mr. Gantt's chart, Frederic G. Coburn thought that one of its chief points was that it would show how much it was costing one for idle time. Granting that seasonal requirements and styles would affect the textile mill, at the same time it was known that goods that had twisted yarns in them cost more than those that did not. If you applied the overhead on the loom-hour basis you would lose sight of that—you would not know how much more one fabric cost than another.

In his line a big boring mill would be idle three weeks out of a month. This chart would tell how much that idleness was costing, and it would give some guidance in going after a line of business that would keep the equipment going, and while his concern did not have to combat styles and seasonal variations and conditions that would bring business for a 16-ft. boring mill, at the same time they would have an eye on the chart and would do better and know how much they failed of accomplishing the desired end.

H. M. Wilcox told of results secured at the Winchester Arms Company from a set of charts similar to Mr. Gantt's, only carried out in a great deal further detail. They had studied the idle machine time in the cartridge-manufacturing department for a year or more, and determined how much time they were losing from the possible productive time of the machines due to tools, to machines, to labor, and to excess equipment. They had carried on that analysis so that they knew how much time they were losing due to keys, due to indexing devices, due to setting up of machinery, and changing over of calibers. This had directed their energy toward the point where they were weakest, in eliminating the idle machine time by giving their foremen information in regard to where time was being lost. They had loosened up a great mass of energy which they really did not know they had theretofore. They had made the jobs interesting to the men without any

[1] South Manchester, Conn.

effort other than pointing out where they were losing time, and had gained vastly in production from the activities of the shop men themselves. They had added to the cost of the idle time the cost of scrap, and called it their cost of lost effort. That had nothing to do with the salable cost of the goods. They gave a report of all lost effort to the foremen weekly, and the foremen had responded in attempting to reduce this waste, which was absolutely all waste, as far as operating interests were concerned. He wanted to mention that, to show that they were all working along the same lines.

SUGGESTED MODIFICATION OF MR. GANTT'S CHART

William Kent thought that in a textile mill it might be possible, if the mill were large and made but one style of goods, so to balance the machinery that none of it would be idle more than, say, 10 per cent of the time; but if many different styles were made, the demand for which varied with the season and with the fashion, the weaving machines might be running full time and not be able to take the whole capacity of the spinning machines, some of which would therefore have to be idle part of the time, or to utilize the full capacity of the finishing, inspecting, and shipping departments.

The "expense actually needed" for the production of a variety of articles might thus include a part of the idle time of machines necessary to have on hand to care for a varying demand, but which could not be kept continuously employed; and in such a case it was right to charge some of the cost of idleness into the "normal burden" which was distributed in the machine-hour rate to the cost of the goods. This rate should be determined annually for each machine, after studying statistics of preceding years, and it should include an allowance for the average or normal time that the machine might be expected to be idle during the coming year. A modification of Mr. Gantt's chart was thus suggested to show how much of the idleness of a machine or department was normal and necessary to the conduct of the business, and how much was abnormal and excessive. This might be done by drawing vertical lines on the percentage portion of the chart indicating the normal percentage of full capacity which each machine or department was expected to run during a month of good business. He also thought the expression "value of the property" used in the paper was ambiguous and that its meaning should be defined.

Referring to Mr. Gantt's chart, John E. Mullaney stated that after his company had used it for about a year, he thought it might be worth while to know that if during the time they had been actually charging expenses to the operation, they had been getting out their product at the fullest efficiency. In order to show that they had tried the idea of drawing a red line adjacent to the black line, the idea being to see if the black and red line agreed. If they did, the production in question had been made at 100 per cent efficiency, that efficiency being based on the standards they had set for their production. The first operation of the chart shown had happened to agree very well. In the next operation the red line fell considerably below the black line, and throughout the rest of them, with four exceptions, were very equally all below the black line. The red ones which extended above were interesting to him, at least, because they showed that they were at this time getting a little better productive efficiency out of these particular operations than they had previously planned.

This particular type of chart of working ideas could be applied to an industry in general, where each factory produced an article, and giving a report to some central head, showing it was efficient, and how much of its capacity it was using and at what rate it was using that capacity; and with a given market and a certain definite product to be manufactured at a given time, it might be possible to so distribute the work that the most efficient man would get the work, and those who were not as efficient in that particular operation would have to swing over to some other operation they could be trained to do more efficiently.

W. C. Brinton thought that the slides which had been shown proved very nicely that in most executive work the problems involved practically every department that existed in most of the large corporations. He believed that, in the case of companies doing a business of $10,000,000 or more a year gross, or companies having a very complex problem of distribution, it was essential for the man who ran a chart department of that kind for the corporation to report to the man who was really running the corporation, no matter what his title was. In many cases the general manager ran the company, or the chairman of the board of directors, but the man who ran the chart department should be able to turn in unbiased reports and tell the actual truth, and bring it out so that the man in charge of the business could see it in all its details, and for that reason the man who ran the chart department should be protected by reporting to headquarters. He believed that money spent in running such a department would give a higher percentage of return than that of any other expenditure which the corporation could make.

According to H. V. R. Scheel, there had been presented for their consideration a principle which was a more fundamental thing than a discussion of ways and means. That principle was that we now had a definite measure of the efficiency of the management. We had broadened our consideration of where responsibility lay, consideration of the efficiency of the individual workman on a machine to a consideration of the efficiency of the whole, for which the management, particularly, had to accept responsibility. In other words, Mr. Gantt's paper showed a criticism of the management, but it was a constructive criticism, inasmuch as it presented itself in a way which enabled the management to correct errors, modify its plans, and lay out a course of procedure which would be more intelligent than any routine way of handling facts heretofore employed.

Written discussions of the two papers, from Messrs. Keppele Hall, Harrington Emerson, E. W. Bemis,[1] Stuart W. Webb,[2] and Henry P. Kendall, were read by the Secretary at this point of the session.

Mr. Hall thought it somewhat refreshing, in these days when so much was heard about the efficiency of labor, to have emphasis laid on the efficiency of management. He believed that most management engineers would agree with him in the opinion that the vast majority of failures to succeed in business were due to the lack of what Mr. Gantt characterized as the "ability to do things" on the part of those really responsible, rather than to any other causes. One could well go a step further and state that in many instances a lack of real knowledge of the vital elements of operation precluded the exercise of this ability by those who really possessed it.

Industrial property, wrote Mr. Emerson, had, according to the point of view, three values; namely, the cost of its reproduction, the amount it would bring under the hammer, and its going value—the real value. This latter was difficult to determine, not because it was not possible on the basis of present

[1] City Hall Square Building, Chicago, Ill.
[2] Vice-President, Old Colony Trust Company, Boston, Mass.

[illegible] and with due allowance for a definite amor-[illegible] to convert net income into capitalized value, but be-[illegible] no one could see into the future far enough to set either [illegible] valid amortization or to determine what next year's profits would justify as increased value.

In industrial concerns Mr. Emerson recommended constant reappraisals based on long average earnings. The valuation from month to month as well as the 10 year average, computed for each month, enabled him to estimate the tendency, thus varying the amortization or obsolescence provision.

If of two plants one was able to operate materials, labor and capital valuation at standard, and each combination of materials, men and capital was yielding the largest margin between cost and sales price, while in the other plant operation was below standard and without reference to difference between cost and sales price, the first plant might very easily have many times the value of the second plant, although inventories were identical.

Mr. Bemis thought that Mr. Gantt's paper did not have a large bearing on the work of the appraisal engineer in rate cases, for in these the attempt was to determine a fair value, which might be quite different from the value based on present rates and earnings. The productive efficiency should have some weight in rate cases; not, however, in determining the value of the property, but in leading commissions to allow a higher rate of return to a company of large productive efficiency, attributable to the excellence of the management, as compared with a business not so well managed.

In the opinion of Mr. Webb, from the operating point of view Mr. Gantt's suggestions regarding idleness expense were highly important. It did not seem to him, however, that this item, which he had usually heard referred to as "load factor," reflected very accurately the value of the plant, due to the fact that so many different things might cause a low load factor. While most of them would probably be due to poor management, there would be other factors, such as, for instance, a distinct change in style (over which the management would have absolutely no control), which might throw a plant that had been operating efficiently entirely out of balance. It seemed to him, therefore, essential to add to the elements of which Mr. Gantt spoke at the end of his paper, "demand for the product and relations to the market (good-will)."

Mr. Kendall wrote that at the Plimpton Press that part of the burden which was not earned through the continuous operating of all or any of the machines, was called unearned burden. If the plant ran its full equipment full time, it had a credit; otherwise there was a certain amount of unearned burden, which was deducted from the profit and loss for each department at the end of each four weeks. He thought that if the net book value of a plant were based on the actual net investment and actual earnings after allowing a proper return on net investment, and costs were determined on a basis of direct expense with only the pro rata per cent of burden applied regardless of whether the entire plant was operated or not, we would then have a common and standard way of determining these three points, which at the present time did not exist.

Oral discussion being then resumed, Robert B. Wolf said that he would like to call the attention of the members to the fact that Mr. Gantt had primarily made a strong plea for organization sanity. The records exhibited formed a method of keeping track of the economic forces in the industry primarily for the purpose of enabling the management to have some record of their progress, and, as he had just quoted from Mr. Polakov's paper, the results produced in the plant depended on how these material forces were used; but unless these records of plant progress were furnished to the management, they could not possibly use these forces intelligently.

We heard a great deal about the efficiency of the workmen, and we were doing a great deal to make them more efficient, but were we giving to the management the necessary information to enable those in charge to become efficient? They were human as well as the workmen, but if we were going to humanize our industries and build men, we had not only to build men at the bottom, but men at the top. He thought that was primarily the keynote sounded in this plea by Mr. Gantt for a greater knowledge of the whole progress of the plant.

H. M. Wilcox stated that he desired to broaden one question, and that was in respect to the granting of industrial credits. They had been shown a way by which the efficiency of the management of an industrial plant could be measured periodically, and he could see very good reasons why the measure of the efficiency of an industrial plant, taken periodically, should be used as a basis for the extension of credit to that organization.

A PLAN FOR THE DISTRIBUTION OF PROFITS

William Kent thought that the whole question of the investment of capital and the returns which should be made upon it, the distribution of profits, had got to come up and be solved in the future, and he wished to offer an idea as to a probable solution. Suppose the Government should pass a law, which should be approved by the community at large, that in shipbuilding or in armor plate or in railroads, or in certain other things, public utilities, or industrial pursuits that had connection with the public—what might be called quasi-public utilities, there should be \$1,000 issued in bonds for each \$1,000 of capital stock, the latter being entitled to a six per cent dividend if earned, the former to 3 per cent interest. A company then should be allowed to earn, without any further investment, 5 per cent, to go into the treasury of the company, so that the company might be able to withstand extraordinary charges due to accidents or floods, etc., or due to having to compete with concerns employing superior machinery, necessitating the company to put in better machinery after awhile or go to pieces. Any excess earnings should be divided, one-half going to the stockholders and one-half to three different parties, the Government, the consumers (by lowering the price or rates), and the workmen who helped make the money.

After calling upon Vice-President James E. Sague to preside temporarily, Chairman Hess took the floor and stated that he did not quite agree that Mr. Gantt's paper was as broad as it apparently purported to be. It really was only a question of detail. It did not make any difference how costs were kept, whether one kept tab on the management, or on the day laborer. Essentially, the thing was to know the costs, no matter what the routine was, or who gave the costs, and after all was said and done the methods of determining these costs were probably as various as the people who were trying to find them out, and probably as various as the industries for which the costs were being kept.

F. J. Cole called attention to the fact that, while keeping all the machines going all the time was of course the economical way, a surplus of machines was sometimes required to take care of variations in product, where the character of the machine work varied considerably with different articles of the same general class which were being manufactured.

W. S. Rogers drew attention to two statements in Mr. Polakov's paper, and recited certain personal experiences by way of emphasizing their importance. The final test of good-will came to a concern when it had to borrow money. He had found that bankers, in investigating the right of a company to ask for loans, had not only desired facts regarding the work done, but also proof that the methods used were the best. They were asking what was the value of the methods, and Mr. Gantt had laid the foundation in detail to lead up to that.

Arthur C. Jackson hoped that some time Mr. Gantt would bring before and show the Society the necessity of charts for a whole industry, and select and define and portray on these charts the definite essentials for the economic operation of that industry, so that each member, each corporation within that industry, would have set up before it the beacons without which they were very apt to run upon the rocks. It seemed to him that this responsibility should lie on the engineering profession, and not, as had been the case in the past, on the lawyers or on the political economists.

The Secretary spoke of visiting recently the Birmingham plant of the U. S. Steel Corporation, and of how profoundly impressed he had been by the attention which the management gave to matters affecting the welfare of the workmen. He spoke also of the interest taken by workmen in production charts that he had witnessed not long ago in a large paper mill, and said that these two observations showed to him a way of tying in the excellent points which had been brought out in the papers: first, the human interest of the managers in the personal needs and health of the workmen, even to their housing conditions, and then, second, making the workmen co-partners in the management of the plant.

In closing the discussion of his paper, Mr. Polakov said that he desired to make but one statement. Admitting that the method of use of the investments and tools of production was the revenue-producing factor, the economic soundness of industry must be a broad criterion as to whether the production was carried out in such a way as to make the men idle and the commodity cheap. If we failed to accomplish either one of these things, we would ruin the country by producing things that could not be consumed, or would limit the production on account of the low purchasing capacity of the consumers.

Mr. Gantt, in closing, said that it was not pretended that his paper contained a complete solution of all our valuation or accounting problems, but it did point the way to detect many of the sources of waste and inefficiency which had heretofore been disregarded, and which could not be detected until we got a proper appreciation of values.

Among the discussions which were particularly significant he might single out that of Mr. William Kent, who seemed to be troubled about the difficulty of fixing a valuation for taxation purposes, if this method of valuation were accepted. This was particularly pleasing to him because, if the methods which were proposed did harmonize with the present system of taxation, he would feel very much discouraged, for there was nothing which was so detrimental to our industries and to prosperity in general as our system of taxation, by which the energy, initiative and business success of the individual were taxed for the benefit of the community, and the wealth created automatically by the community was allowed to go, without any return, to individuals who, as a rule, were contributing nothing to that community. If the wealth created automatically by the community should be claimed by the community, it was highly probable that it would be unnecessary to tax any of the industrial activities of individuals, and Mr. Kent's troubles would absolutely vanish. If the proposed system of accounting had a tendency to make that factor clear, it would do much to lift a burden from our industries and enhance the prosperity of the workers.

If we would meet the competition with which some of us thought we would be so direly threatened after the war, we must encourage industry and discourage idleness, for the warring nations, having found what an enormous increase in strength such a procedure had given them, would hardly return, when the war was ended, to the other method which we seemed to cherish so highly.

Arbitrary laws based on opinions inherited from a bygone age were not suited to an age like this, when the struggle for existence, which was so keen in Europe, threatened, perhaps in another form, to involve us; for the same causes that were active there were active here.

Ninety years ago Thomas Carlyle had said, "The tools to the hands that can wield them."

It was a reversal of this policy which more than all other causes combined had brought Europe to such dire extremity. The control of the implements of production had fallen into the hands of investors, who saw more profit in the control of markets than in productive efficiency, which they did not understand.

Competition for the control of markets was at bottom the primary cause of the great war, and the fact that Germany had had a somewhat clearer comprehension of the importance of productive efficiency and the necessity for the control of tools by the hands that could wield them, was the explanation of her tremendous industrial and military power.

During the last eighteen months England had revised her policy, and through her Minister of Munitions had taken industrial control from stock and bond holders and placed it in the hands of those who could "deliver the goods." The development she had made since this change was so phenomenal as to be almost unbelievable. In her attempt to save her life she had learned that strength lay in productive efficiency. The other European nations had undoubtedly learned the same fact.

In the face of these examples were we still going to pin our faith to market control, until aroused by a catastrophe, or could we learn from the fate of others and begin at once to develop productive efficiency? We had been talking efficiency in this country for over ten years, but so far the results had been lamentably small. This was not the fault of the workmen, for wherever we had had efficiency at the top we had had but little difficulty in training workmen to be efficient.

For years, with inefficiency at the top staring him in the face and hampering him at every turn, he had labored to find a means of measuring that efficiency, as it was perfectly evident that without efficient direction, efficient workmen were ineffective, even if it were possible to get them, which it usually was not.

If we could measure and evaluate the productive efficiency of the manager as we now measure that of the workman, we might hope for better results.

The only men organized for the promotion of productive efficiency were the engineers, and it was on their shoulders that must fall the burden of showing what could be done.

He offered as a part of this work the chart shown in his paper as an attempt to measure the efficiency of the executives, and to indicate in a general way their value, which we knew was an integral part of the value of any successful industrial property. This was only a first attempt, and he noted that already one engineer had taken a step beyond what he offered.

GAS POWER SESSION, THURSDAY AFTERNOON

THE Gas Power Session met on Thursday afternoon for the consideration of a program of papers arranged by the Sub-Committee on Gas Power, of which H. J. Freyn is chairman. Mr. Freyn was unable to be present and Prof. William T. Magruder conducted an exceedingly well-ordered meeting. The attendance was upwards of 150, and the papers were of such interest that the session continued until 5:30. Mr. Freyn sent the following telegram to the acting chairman:

"Regretting deeply inability to be present, am sending my best wishes for a successful session, with many thanks to yourself and greetings to all."

O. C. Berry[1] presented the first paper, on A Gas Producer for Bituminous Fuel, pointing out the essential features of a producer designed and experimented upon by himself. The paper was the subject of considerable oral discussion.

Because of its tar content, the author contended that bituminous coal could not be used in a standard updraft producer like anthracite. As even more satisfactory than either a down-draft or double-zone producer, he described a recirculating producer, discharging its gas near the middle of its height and returning the products of distillation above this point to the combustion zone at the bottom. The steam which must be supplied for the gasification process was introduced through a steam-jet blower and provided the means of circulating the gases.

A second line of investigation was to determine the proper temperature for the recirculated gases to precipitate the least tar, and between 300 and 450 deg. cent. (550 to 900 deg. fahr.) was found to be the preferred range.

The remainder of the paper described the recirculating producer designed by the author, an account of which appeared in The Journal for December.

DISCUSSION OF MR. BERRY'S PAPER ON A GAS PRODUCER FOR BITUMINOUS FUEL

In a written communication, Godfrey M. S. Tait said that the methods for the determination of the tar content were all highly practical as applied to the experimental apparatus used, but would have to be modified in connection with the test of a plant in regular service.

He said that the theory as to the volume of the recirculated gas was not original, having been tried with more or less success in Europe. The main difficulty was with the power consumed by the blower and the excessive quantity of steam thus introduced, unless some arrangement were provided whereby the governor of the engine might control the supply of steam.

The findings as to clinkers were apt to be misleading, due to the very small size of the producer. Any arrangement to get away from the balanced draft condition greatly increased the tendency to clinker in all kinds of fuels. The clinker was first formed by a fissure in the fuel bed through which there was a concentration of draft. A large fuel bed and grates that insured an equal distribution of the draft current to all parts of the fuel was the only way to prevent clinkers.

In practice, it would be found that the resultant increase in efficiency due to the fixation of the tarry vapors of the gas rather than to wash them out and waste them, was much less than would be expected.

Personally, he leaned to the construction of bituminous producers along the line of the simple single-zone up-draft type with attached tar washers as being better adapted to the hard usage of practice.

As to the reduction of CO_2 to $2CO$, Mr. Tait's experience indicated that a perfect reduction occurred at 1800 deg. fahr. provided that the draft velocity was sufficiently low to allow the time necessary for the reaction.

He thought Mr. Berry should continue the investigation under conditions entailing more commercial conditions, variable load without special attention, and noting the possibility of keeping the gas tar-free during such variations without attention, the effect of large areas of the grate, etc.

In an oral discussion, Edward Rathbun said that while Mr. Berry's investigation appeared to be an excellent laboratory development, the actual gain in practical knowledge, as an aid to present commercial operation of producers, was somewhat limited. He called attention to Mr. Berry's statement that the gas was "nearly as clean as anthracite gas," and said that in order to develop the producer-gas engine, the gas must be clean, and that gas nearly as clean as anthracite was not clean enough.

Mr. Rathbun pointed out that in breaking up the methanes, the heating value of the resulting gas was low and that the capacity of the engine of a given bore and stroke was thus reduced and the flexibility of operation desired was not obtained.

Without question, said Harry F. Smith in discussing Mr. Berry's paper, the complete oxidation of the hydrocarbon content of the coal, the water vapor and the carbon dioxide, and the subsequent dissociation of these fixed gases and the carbon, constitutes an absolutely effective way of eliminating tar.

He pointed out that unless a coal contained a high percentage of fixed carbon there was not enough fixed carbon in the coal to carry on a recirculating process continuously in a producer. If the producer was running for several hours with sufficient stand-by periods, enough coke would be formed during these periods to cover the deficiency in carbon. One way to overcome the difficulty was to permit part of the products of combustion to pass out of the producer undecomposed, with a consequent loss in efficiency.

The objection to low heating value, mentioned by Mr. Rathbun, was of even more importance if the gas was used for industrial operations, such as brazing and forging. Since there were several methods available for cleaning producer gas, the removal of the tar was so easy and effective and the apparatus so simple that the justification of a more complex producer with the uncertainties of the process was questionable.

A uniform gas from soft coal was difficult to obtain, W. B. Chapman said in discussing the Berry paper. In his experience covering a period of twelve years Mr. Chapman had met with all the difficulties mentioned by Mr. Berry and more, and was not sure, in his own mind, that the problem of obtaining a gas from soft coal, suitable for gas engines, could be solved along the lines outlined in Mr. Berry's paper. The fuel bed of the Berry producer was too deep for easy poking, a disadvantage in practical operation. Unless there was some means of controlling the circulation of gas when the engine was under a light load, the fire would grow cold because of the returning gases.

In his oral closure, Mr. Berry referred Mr. Tait to the determinations of the United States Geological Survey in the

[1] Purdue University, Lafayette, Ind.

matter of the temperature necessary in practice for the decomposition of carbon dioxide. He explained that in testing the gas for tar, the gas was made to impinge upon a card, any tar in it showing a dark mark upon the surface of the card.

The gas was probably not all burned in the bottom of the producer, but it must be evenly distributed over the area at the bottom in order not to form cold paths between the grate and gas outlet. The gases could be cracked very effectively by passing through an incandescent zone, and, under a light engine load, the gases were simply cracked and the carbon monoxide passed through without being turned into carbon dioxide and then into carbon monoxide again.

The plant as operated ran ten hours a day under full load, was not operating at night, and was started the next morning after twenty-five to thirty minutes' blowing. It was never run for ten hours consecutively for more than a week.

MR. SWAIN DISCUSSES THE COMMERCIAL SAMPLING OF PRODUCER GAS

Philip W. Swain read an abstract of his paper on The Commercial Sampling of Producer Gas. He said that, as a rule, the sample of producer gas to be analyzed should be drawn from a pipe in which there was a continuous flow of fresh gas from the main. For a correct continuous sample, a number of conditions must be observed: namely,

a There must be no variation in pressure in the gas entering the sampling bottle

b The sampling pipe must draw from the main a sample representing the average gas over the entire cross-section of the main

c The sample should be drawn at a rate proportional to the flow of gas in the main. If the variations are not great, a sample drawn at a constant rate will approximate closely the correct sample.

Although a very good snap sample could be drawn using the ordinary two-bottle method of sampling, this method could not be used very well for proportional sampling, and was not reliable even for uniform sampling. The author described and illustrated a device which he had designed and used, and which permitted the accurate measurement and control of the flow of water from the sampling bottle.

There were several portable instruments on the market, modifications of the Orsat apparatus, which had means of determining not only the carbon dioxide, oxygen and carbon monoxide, but also the hydrogen, methane, and sometimes illuminants as well. In such instruments, the hydrogen and methane were usually determined by explosion with air. To avoid the various difficulties of determining carbon monoxide by absorption, the carbon monoxide might be determined by explosion with the hydrogen and methane. This involved a little more computation, but the labor might be minimized by standardizing the method and making use of a diagram which the writer had prepared.

Lack of interest in gas analysis, said W. E. Renling[1] in a written discussion, doubtless came from two causes: first, failure fully to appreciate the fact that a gas analysis, when properly interpreted, furnished a splendid check on the efficiency of the plant for the conditions under which it was being worked; and, second, from a rather inherent feeling that the subject of gas analysis was rather too technical, or savored too much of the chemical laboratory, to be really a friend and working tool for the practical engineer, owner or operator. It would be only through broader education and discussion that fuller appreciation would be given this subject.

It was the opinion of H. F. Smith that everything the author had said meant something to the fellow who had been up against the practical side of this work. However, he wanted to caution against the general statement that a good idea of the quality of the gas might usually be obtained from the carbon dioxide alone, to emphasize which he read from a number of analyses made by the same chemist, in the same plant, by the same method, and on gas from the same coal. The extreme variation in the carbon dioxide content, percentage of combustible and heating value gave evidence to show "that it is not always possible to depend on the carbon dioxide indication alone."

In his oral closure, Mr. Swain pointed out that there was considerable difference of opinion among men with wide practical experience as regards carbon dioxide as an index of gas quality, some being so certain that it was an indication of gas quality that only carbon-dioxide determinations were made by them.

In answer to a question by S. A. Moss, Mr. Swain said that it was quite important to have the velocity of the gas in the sampling tube the same as that in the main pipe if the dust or suspended matter in the gas was to be determined; but as the analysis was of a fixed gas which had passed through a scrubber and presumably was well mixed, there seemed to be no necessity for sampling at the exact velocity of the gas in the main. The idea was to take a sample continuously, and to take it at all times in proportion to the rate of flow of gas through the main, so that the final sample would be the same as though all the gas had been drawn off and then a sample obtained from it.

PROFESSOR EARHART TREATS OF CERTAIN NATURAL GAS PROBLEMS

The next paper in order was on The Ratio of the Specific Heats and the Coefficient of Viscosity of Natural Gas from Typical Gas Fields, by Robert F. Earhart. An abstract of this paper appeared in the November, 1916, Journal, to which the reader is referred.

In a written communication upon this paper, Harold B. Bernard said that, due to the many features encountered in piping natural gas, such as condition of pipe, type of joints, bends, temperature changes, etc., it was doubtful whether Professor Earhart's determinations were of value outside the laboratory. For practical conditions, the formulae derived by T. R. Weymouth[1] from numerous observations were unquestionably of sufficient accuracy for problems involving the flow of natural gas.

A recomputation of densities of the author's Table 1 was also given. The new densities were computed from the fact that the densities were as the squares of the relative coefficients of viscosity, the coefficients of viscosity being in the ratio of the times of efflux. It is expected to give later publication to this table.

P. F. Walker, in a written discussion, said that paper was an interesting illustration of the application of scientific methods of analysis to technical problems. It was a variation from the methods which were commonly employed in the discussion of engineering problems, and it was a significant thing that work upon which the engineer was now engaged was being treated in many lines with a degree of accuracy

[1] M. E. Dept., Michigan Agri. College, Lansing, Mich.

[1] Trans. Am.Soc.M.E., vol. 34, p. 1091.

[illegible] Germany, the employment of the [illegible] on the [illegible].

[illegible] the words "ratio of specific heats," [illegible] discussion showed that he was [illegible] the value of the adiabatic exponent [illegible]. It was here that the trouble would begin. It seemed [illegible] necessary to go through the steps of the mathematical proof of the principle that for a perfect gas the adiabatic exponent was the ratio of the specific heats. It had been his observation on several occasions, however, that it was necessary to remind engineers of the fact that the statement applied only to perfect gases. It seemed to be ingrained in the minds of technical and scientific men that the adiabatic exponent must be the ratio of the specific heats. The point brought out in the previous paper by the author, and in substance fully attested to by all who took part in the discussion, was that this gas in its behavior did vary materially from the laws of perfect gases, and hence it must follow that the value of the exponent found for an adiabatic cannot be taken as the ratio of specific heats.

W. D. Ennis opened the oral discussion by stating that while the value of n for the adiabatic curve might be determined from compressor indicator diagrams, no engineer believed that this was the ratio of specific heats. He also pointed out that there must be some error in the author's determination of n, as in some cases it is less than the value of n for any of the constituents of the gas.

As to the author's method of procedure, there seemed to be nothing wrong, except that the determination of n for the gas as a function of that for air by comparing the wave lengths would have seemed more conclusive if the apparatus had been tried out on some other gas, such as carbon dioxide, for which the value of n was known.

Sanford A. Moss showed that the value of n could be computed from the gas analysis from the expression

$$n = \frac{X_1 C_{p_1} + X_2 C_{p_2} + \text{etc.}}{X_1 C_{v_1} + X_2 C_{v_2} + \text{etc.}}$$

Commenting upon the written discussion offered by H. B. Bernard that the densities are proportional to the squares of the times of efflux, Edgar Buckingham said that the statement is at the bottom of Bunsen's method of determining the relative densities of gases by means of efflux through small orifices. The statement was not theoretically correct nor did it give correct values in practice. Bunsen's method is an approximate, not an accurate one, and his own determinations are correct only within five or ten per cent.

As the author was not present, it will be necessary to defer the publication of his closure.

POTTER AND BUCK'S TESTS OF GAS AND OIL ENGINES USED ON TRACTION ENGINES

Also, the authors of the next paper, A. A. Potter and W. A. Buck,[2] were unable to be present. This paper was upon An Investigation of the Internal-Combustion Engine as Applied Traction Engines, which was instituted to determine fuel economy and thermal efficiency of different types of motors used in traction engines. The following conclusions were [illegible]:

[illegible] motors were better adapted to belt work; single-[illegible] and two-cylinder motors operated better than [illegible] motors with fuels heavier than gasoline.

Piston speeds should be lower than in automobile motors, speeds of from 700 to 900 ft. per min. giving satisfaction.

The valve-in the head type of motor had the more efficient combustion space and was to be preferred to the T head or L head types.

The jump-spark system of ignition was to be preferred on account of its mechanical simplicity.

The fuel-economy range was from about 1.3 lb. per b.hp. per hour at one-fourth load to about 0.7 lb. per hour at full load. The fuel consumption in pounds per hour per brake horsepower was very nearly the same for both gasoline and kerosene.

The thermal efficiencies at full load varied from 14.88 to 19.41 per cent for gasoline fuel, and from 13.7 to 15.97 per cent for kerosene.

Carburetors now used are satisfactory for gasoline, but a carburetor jacketed with heat from exhaust gases should be employed when operating with kerosene or with heavier fuels.

The results of the tests show the advantages of kerosene as a fuel. For a group of motors developing 26 b.hp. and under, at full load, with kerosene at 10 cents per gal. and gasoline at 20 cents, the cost of operating with gasoline was 1.99 times that when kerosene was used. Similarly, for a group developing 51 b.hp. and over, at full load, the cost with gasoline was 1.62 times that with kerosene. The advantages of the kerosene-burning motor were somewhat offset, however, by the added trouble in handling and by the shorter life of the motor when operating on such fuel.

W. D. Ennis said that he was particularly interested in the reported economy of the engines tested, which averaged not far from 0.8 lb. This was a strikingly favorable figure as compared with the hot-cap engines of the semi-Diesel type in which liquid fuel was injected as a liquid into the cylinders. These hot-cap engines, at about 50 lb. compression, used about 0.9 lb. of kerosene per b.hp-hr., and just about the same amount of fuel oil of the usual Eastern grade. It was an interesting question whether the extraordinary economy of the carburetor type of engine as presented in the paper, was due to a higher compression than 50 lb. or to better combustion. He said that he did not believe it would be generally admitted that with equal compression and the same fuels the hot-cap engine was inferior in economy to the engine of the carburetor type.

The program concluded with an Illustrated Review of the Development of the Werkspoor Marine Diesel Engine, by Thomas O. Lisle. This has not yet been published in The Journal, but it is planned to give later a comprehensive account of the lecture, with illustrations selected from those used for the lantern slides.

In answer to a question by A. J. Wood, about the relative weights of two- and four-cycle marine Diesel engines, Mr. Lisle said: "It has been found in marine work that the four-cycle engine is rather lighter, owing to the extra parts necessary for the two-cycle, particularly the scavenging pump. Theoretically, the two-cycle should be much lighter, but of all that have been put into service, the two-cycle have been heavier than the four-cycle."

Julius Kuttner[1] asked about the strength of the reversible propeller used on some Werkspoor boats, and was answered that the strength was a matter of design.

MISCELLANEOUS SESSION, FRIDAY MORNING

At the general session on Friday morning an address of absorbing interest was delivered by Wm. L. Cathcart[1] on the Development of Our Fleet and Naval Stations. This was illustrated with lantern slides showing vividly the needs of our navy, particularly with respect to naval stations and naval bases, and was supplemented by a general discussion to which valuable contributions were made by Rear-Admirals John R. Edwards and Bradley A. Fiske; and by President D. S. Jacobus and President-Elect Ira N. Hollis. It is expected that the address and discussion will constitute a leading feature of the February issue of The Journal.

MR. CATHCART SOUNDS NATIONAL NOTE ON COUNTRY'S NAVAL NEEDS

Mr. Cathcart said that the elements of naval strength are its ships and men and its shore stations; he showed by means of diagrams how important are naval bases for the protection of our vulnerable coast; and how the location of such bases and naval stations on our own coast with respect to our possible battle grounds of the future are of primary importance. For the maintenance of our navy we needed a large number of navy yards with channels of approach dredged to full depth and with modern equipment for building both hulls and machinery. Reliance must be placed both on mines and submarines for the protection of our harbors, which in turn must be protected by shore batteries or the guns of a fleet.

Mr. Cathcart discussed certain features of interest alike to artillery officers and engineers, such as modern battle ranges, with comparison between the effectiveness of 14-in. and 16-in. guns; fire-control methods, the foundation of which was the successful application of the telescopic sight to naval guns; the possibilities of modern guns and powders, and the degree of excellence of marksmanship in our navy.

He contended that the navy should not be for aggression but to keep peace and to exert what Mahan called the "silent force of sea power," for which a large navy would be needed.

The address made a deep impression upon those present and there was a general feeling of approval and a very evident responsiveness to the convincing presentation by Mr. Cathcart of the nation's needs.

Rear-Admiral John R. Edwards[2] stated that the author's paper was one of the strongest he had heard in the last decade. In view of the fact that he had served as General Inspector of Machinery for the United States for all machinery built on the North Atlantic Coast, he was familiar with every shipyard and with the various shore stations on this coast. He therefore dwelt on the needs of these stations and gave constructive suggestions for their further equipment, of which they are so much in need.

He said that if were were to construct ships we must have facilities for repairing them. There must be docks large enough to take modern men-of-war, cranes heavy enough to lift the immense guns or the turrets off from a ship; deep piers at least 100 ft. wide; dry docks 1000 ft. long; and other equipment in proportion, not forgetting the need for hospitals and dispensaries.

Taking Charleston's harbor as an illustration, the thought was preëminent in his mind that we could allot without reservation the value of either one battleship, battle cruiser, two scouts, or ten destroyers, if necessary, in order to build a modern station at that point. The other countries of the world would measure our strength not alone in battleships but in our facilities to build battleships and to repair and equip them.

The history of Gallipoli and Salonica showed that there must be miles of water front in order to move a modern army, as a result of which the naval engineers of France and England were building large naval piers sufficient to accommodate 50 transports at one time. The need for such piers applies to both distant bases and to those at home, including the base at the Canal Zone.

He reviewed what England had done through the past five years in upbuilding its naval stations, beginning at the Firth of Forth, and what Germany had done at Wilhelmshaven and Heligoland; work of vast extent and of tremendous scope which had many times proved its worth since the beginning of hostilities. These developments certainly constituted a striking object lesson to American naval officers and engineers.

Rear-Admiral Bradley A. Fiske said it was unfortunate that the people of our country did not realize the danger to which they will be subjected when the nations at war agree on terms of peace and arrange what they will do in order to overcome the financial disaster which is threatening them. The people in our country at large believed there was no danger, and were ignorant as to what might be required to insure the safety of the country. It was the duty of every member of the Society to use his power and influence among his associates and acquaintances to show them, by the aid of the accurate thought and language to which engineers are accustomed, what the actual danger was and what the requirements were for national defence.

Dr. D. S. Jacobus emphasized the duty of the engineer to enter into public affairs. He should take more interest and do more in performing his civic and governmental duties. The attitude of the Society has been that it should not undertake anything except strictly engineering work, but times are changing, and we should consider whether the Society should go further than this. Possibly it would be better for engineers from different societies to combine for the purpose of dealing with important public matters and show what engineers can do through coöperation, something after the order of the work done in connection with the industrial census. He felt that the day is not far distant when either through the action of the existing societies or through some other organization engineers will take their true place in the management of affairs.

Prof. M. E. Cooley, speaking from the standpoint of an educator, said that the impression existed that the Naval Academy was the only institution which fitted a young man for naval service, and West Point the only institution [illegible] service. He had recently had occasion to compare the curriculum of the Engineering College [illegible] with that at Annapolis and also at West Point [illegible] the highly specialized training [illegible] in both of these institutions [illegible] very essential. He found that [illegible] engineering school paralleled about 85 per cent, [illegible] possibly more, of what was given at Annapolis and West Point. In other words, by adding about one-half year more of work or by substituting one-half year's work in place of other subjects, young men could be turned out from our engineering colleges with the same general training with which they were now trained at either Annapolis or West Point.

[1] 636 Westview Ave., Germantown, Philadelphia.

[2] Bristol, R. I.

Dr. Ira N. Hollis referred to the participation of the Society in public affairs and said that he not only approved of it but thought that the continuation of the organization as a useful function of society was absolutely in that direction.

There had been a great deal of interest in the United States in preparation for war, or military preparedness; but he looked upon preparedness as a very much larger matter. He would strengthen the conception of service by leaving out the word "military" and extend the work of preparedness to all public and private affairs that are in any way related to the larger success of the nation.

A friend in command of one of the large naval stations had written suggesting that civilians ought to serve for a short time every year as understudies in the conduct of naval manufacture and repairs, so that men would be trained during peace to take charge of the work in time of war, thus relieving officers who were prepared in the more technical details. That illustrated the direction in which we should work and suggested the organization of an Engineers' Reserve composed of members of our Society for all purposes behind the fleets in making the supplies for the Navy and in training for war service.

Was it not a duty of every young man to give, freely, one, two or three years of service to his country, no matter whether that service took the shape of learning how to fire a gun or going into public service for the purpose of building ways of communication between the different parts of the country?

Any young man should feel proud to serve on a Lincoln Highway after enough experience at Plattsburg to teach him obedience and the democracy of the barracks. Two years' digging for his country, as a free contribution towards means of communication, would be as important for peace as for war. The pick and shovel could be made as effective in promoting love of country as the rifle, and every youth ought to have a taste of them.

Brief remarks upon Mr. Cathcart's paper were made also by Carl G. Barth, M. A. Stone and F. G. Coburn.

MR. COBURN DESCRIBES NAVY METHODS OF HEAT-TREATING WROUGHT-IRON CHAIN CABLE

Following the presentation and discussion of the paper on naval preparedness, a brief abstract was presented by Fredk. G. Coburn,[1] of an important paper on Heat Treatment of Wrought-Iron Chain Cables, prepared jointly by Messrs. Coburn, W. W. Webster and E. L. Patch.

All the chain cable for the U. S. Navy is made in the smith shop of the U. S. Navy Yard at Boston under the direction of Naval Constructor Coburn. This chain was formerly hand-forged, but it was finally decided to adopt power forging, after which considerable difficulty was experienced through the frequent failure of the chain links. It was evident that some form of heat treatment was necessary, and as there was practically no information available on the heat treatment of wrought iron, which was used in the manufacture of the chains, an extensive investigation was conducted. It was found that annealing under certain conditions relieved the stiffness which apparently existed in the links and to which their failure was attributed.

Preliminary to the tests upon the links themselves, tests were conducted upon the material used in the manufacture of the chain, in the way of chemical analyses, tensile and impact tests and metallographic examination.

The paper gives the results of these several series of tests, a summary of which will appear in an earlier issue of The Journal.

STEAM BOILER SESSION, FRIDAY MORNING

A LONG and highly profitable session was held on Friday morning under the auspices of the Boiler Code Committee. The audience, though small at first, grew in size until at last it taxed the seating capacity of the room. At the request of John A. Stevens, Chairman of the Boiler Code Committee, Professor A. M. Greene, Jr., acted as presiding officer, assisted by Sherwood F. Jeter. In addition to the three scheduled papers, two topical discussions were presented upon the subject of welding.

The first paper, upon An Analysis of Marine Safety Valves, with Suggestions for Repairs and Improvements, by E. F. Maas, considered the various elements of safety valves which had to do with the successful operation of the valve. Seven typical valves were discussed with respect to the following points: Tightness; pop of valve and simmering; lift of valve; closure and chattering; blow-down and its adjustment; discharge capacity; repair and adjustment.

The author believed the flat-seat valve superior to the beveled-seat valve, contending that it was as easy to grind and would more generally remain tight. He showed how certain valves provided with adjustable blow-down might be rebuilt so that when repaired the necessary machining would be small and need not be done to a standard gage. The paper contained many suggestions of practical value for the grinding and repair of safety valves.

Charles W. Barnaby opened the oral discussion of the Maas paper by asking why all manufacturers of safety valves used a square rod for valve springs when it had been discarded for springs for practically all other purposes.

A. A. Cary answered Mr. Barnaby's question by saying that it was possible with the square-rod spring to get more resistance in a given volume. The round spring was theoretically the best. The principal resistance was to torsional movement. The square spring occupied less space, was more rigid, and better adapted for pop valves in every way. It held its shape, and manufacturers who had used round wire and bar springs always came back to the square springs.

MR. TALBOT DESCRIBES HIS MARINE TYPE OF BOILER WITH FORCED CONTRA-FLOW CIRCULATION

Assisted by lantern slides with which to illustrate his paper, Paul A. Talbot[1] gave a descriptive talk upon the boiler which bears his name. This boiler utilizes the principle of forced contra-flow circulation through water tubes at high velocity. Steam drum and water drum are unnecessary, so that danger from explosion is reduced to a minimum. Oil is sprayed by superheated steam into the combustion chamber, which is lined on all sides with heating surface.

The supply of feed water passes through a regulator valve before entering the boiler. This valve is controlled by the expansion of one of the tubes of the boiler so that it opens and closes with varying temperatures of the steam within the tube.

[1] Pres., Talbot Boiler Co., New York City.

The fuel valve is also controlled by the expansion of this same tube so that the fuel supply is cut off if the temperature of the steam becomes greater than is desired. The control of feed and fire thus becomes automatic. A gage is provided for indicating to the operator the relative temperature of the steam.

The high velocity of water and steam over the heating surface prevents the formation of scale. Steam jets are provided for blowing soot from the outside of the tubes.

A high rate of evaporation is obtained, the average, including economizer and superheater surface, being 8 lb. of water per sq. ft. (16 lb. on forced draft).

Because of the contra-flow principle, the effect of increased draft and higher evaporative rates is to increase the economizer surface of the upper tubes and to modify the stack temperature.

In a written discussion, Albert A. Cary commented upon the similarity in construction of the Talbot boiler and the Niclausse boiler, which had the same field tube arrangement. His personal experience had taught him the desirability of having the water storage made a part of the boiler, which provided to a certain extent an immediate source of water supply, when the combustion in the furnace was quickly increased to meet a sudden demand for steam. The tendency of many inventors in producing compact water-tube boilers, especially those of the marine type, had been either to reduce greatly the size of their steam and water drums, or else to do away with them altogether; and it was still an open question as to how far this could be safely and rationally done. In the Talbot boiler, automatic regulating devices did away with water storage.

While the Talbot boiler did not better the Niclausse boiler in exaporative rate, it required considerably less space per unit.

His experience did not lead him to believe that there was solid water within all the tubes of the Talbot boiler when it was in operation. Tests made in England on the Belleville boiler, of somewhat similar tube arrangement and forced water circulation, had shown that 50 per cent of the boiler under normal conditions was filled with steam. Judging from this, it was safe to assume that a considerable lower portion of the Talbot boiler was filled with steam during operation, and such steam-bathed surfaces could hardly be considered good water-contact heating surfaces, i.e., efficient for the production of steam.

He believed in the contraflow principle in operating boilers, providing it could be accomplished by simple means and without too great an expenditure, or inaccessible moving parts.

Extended experience had taught him that the highest results for heat transmission in boilers were secured by removing the steam from the heating surfaces almost as rapidly as it was formed, and thereby permitting the greatest possible area within such heating surface to be bathed and wetted with solid water. In this type of boiler, which prevented the steam formed in the interior of the boiler from escaping from the heating surface, we were certainly not improving the conditions required to facilitate rapid heat transmission through the lower and most valuable area of the heating surface.

The danger of scale in a boiler equipped with field tubes was brought out by Mr. Cary, who said that although there might be a sufficiently high velocity to prevent scaling when the boiler was in operation, there were periods when the boiler would be shut down and when the scale might accumulate so persistently that the circulation of the water, upon resumption of operation, would not be sufficient to remove it.

Capt. C. A. Carr, U.S.N., said that the first tests of the Talbot boiler for the navy showed particularly good results in the reduction of the quantity of oil burned and the increase in speed of the boat. It was believed that in this case the economy was caused directly by furnishing dry or superheated steam to an engine which previously had been very wasteful through the use of wet steam. The use of the Talbot boiler appeared to furnish a ready, reliable, convenient and inexpensive means of supplying steam of any desired degree of superheat for small power installations in which oil was used as fuel.

Perfect control of the feed system for this type of boiler was essential. On account of the small reserve capacity of steam and the friction of steam and water in the boiler, the feed pumps usually furnished with small marine plants would be found unsatisfactory. The automatic control valves were intended for use when the engines were running steadily. When working to bell signal, the oil supply and feed valves were necessarily regulated by hand.

Captain Carr considered the oil-burning system furnished with the Talbot boiler unsuitable for large boilers and wasteful of both oil and steam with small ones.

Prof. R. C. Carpenter said that a study of the White boiler plant in connection with the Talbot boiler should prove of interest. He made reference to a paper which he presented in December, 1906, and which appears in Vol. 28 of the Society's Transactions, dealing with his tests of the White automobile boiler.

John W. Parker spoke of the difficulties he had experienced with his early investigations of boilers of the general type of the Talbot boiler, particularly with the scale formed by the insolubles in the boiler water. He showed how Belleville, who attempted for a long time to build a water-tube boiler without any drum, finally installed the drum, later introducing a gravity circulation independent of the pump, and at last succeded through perfected automatic control devices. If the Talbot boiler succeeds, he believed it would depend on the efficiency of the automatic devices for its success.

In his oral closure, Paul A. Talbot pointed out that the particular advantage of the field-tube construction was the relieving of the strains due to the expansion of tubes between tube sheets. He showed that in the tubes in his boilers, the expansion under a temperature of 800 deg. fahr. was as great as one-half an inch. The high velocity of circulation under extreme firing conditions, he said, keeps the boiler cool.

Speaking of the deposits in the boiler tubes, Mr. Talbot stated that even with the water of Puget Sound in the boilers there was no accumulation of scale in the tubes. After standing all night, there was a small amount of silt in the tubes, but this was swept away as soon as circulation was set up. The high velocities would damage by erosion, rather than corrosion. There was never any formation of sediment noted when the tubes were examined after the boiler had been shut down.

In answer to a question put by D. K. Warner[1] about limiting the draft to two inches, Mr. Talbot said that two inches was not a limit. Lack of time and money have prevented experiments with forced draft.

The tube referred to in the original paper which was removed in 61 sec. was chosen at random by the officers in charge of the test as the one they wished changed. All of the tubes were accessible, but it was not possible always to change a tube in as short a space of time as this.

[1] Sheffield Scientific School, New Haven, Conn. Graduate Student

[illegible] later was answered that the change in the con[illegible] header was made because it simplified the construction and for no reason which affects the operation of the boiler. (This change in construction was illustrated in one of Mr. Talbot's slides and did not appear in the illustrations accompanying the original paper. It referred to the cored passages of the header.)

MR. PARKER OUTLINES THE DEVELOPMENT OF HIS DOWNFLOW TYPE OF STEAM BOILER

The downflow type of steam boiler was discussed at length by John Clinton Parker in a paper bearing that title. With the aid of lantern slides, Mr. Parker presented an interesting lecture.

This paper describes the early experiments which demonstrated the possibility of circulating the water in boilers apparently contrary to the natural way, that is, downward rather than upward. From these there was developed the downflow boiler which was designed and had been built by the author for a number of years.

Among the advantages of the downflow principle was the fact that the course of the water and steam were opposite to those of the flame and hot gases, consequently the hottest particles of each were in communication with the hottest particles of the other and there was a minimum difference of temperature between the adjacent particles of the two.

The tubes are formed, by connecting their ends together through junction boxes, into a number of vertical coils, and one of the special problems of the manufacture of this boiler was the design of these junction boxes. The paper described these boxes, which were constructed of malleable iron.

A. A. Cary opened the oral discussion by making objection to the location of the superheater in the Parker boiler, which was placed in the combustion chamber near the bridge wall. The superheater, he said, was a secondary apparatus, and after the boiler had absorbed all the heat possible, the waste gases were led away to superheat the steam. In this way, one did not deprive the boiler of any of its functions. He also pointed out that the efficiencies obtained with the Western coals in the St. Louis tests, quoted by Mr. Parker, were not as high as would be obtained with Eastern coals.

In his closure, Mr. Parker cited Rankine as his authority for placing the superheater. He deprecated efforts of manufacturers to establish exceptional boiler performance under conditions not readily obtained in practice, and stated that he had made it a rule to compare his boiler with others under ordinary working conditions.

MR. WILDT DESCRIBES THE PENCIL ELECTRODE METHOD OF WELDING

E. A. Wildt[1] gave an illustrated talk dealing with The Pencil Electrode Method of Welding. The manuscript was received too late to appear on the program, but was presented at the request of the Boiler Code Committee in order that this important subject might receive a general discussion.

The object of the paper was to educate engineers on the matter of welding, by a description of the pencil electrode method which was used for boiler joints. The author wished the Society to consider whether it was more feasible to weld the joints of a boiler drum than to rivet them with a butt strap joint.

[1] Lackawanna Boiler & Grate Co., Scranton, Pa.

The success of any weld depended upon bringing the pieces of metal to the proper heat. Electricity was used only to supply the heat, and in the pencil method only just enough heat was obtained to accomplish the joining of the two metals. Regardless of whether the voltage or the amperage were uniform, a metal wire used as part of the circuit always formed one terminal and provided the welding metal.

The temperatures obtained in gaseous and electric-carbon welding wherein fluidity of both metals was a condition, were 2800 to 3000 deg. fahr., while in the electric-pencil method the temperature did not rise much more than 1500 deg. fahr., which was only enough to produce a plastic condition.

The forge welding, approved by the A.S.M.E. Boiler Code, caused heavy expansion strains, so that when the forge-welded seam had cooled off, the adjacent expanded metal produced tensile strains tending to pull the welded portions apart. The pencil electrode and the forge method were alike in the fact that in neither was the metal heated beyond a point necessary to produce a weld. That which prevented the high temperature in the weld was the fact that as fast as the metal to be added to the weld became plastic, the pencil must be advanced toward the work to close up the spark gap, the current otherwise being interrupted. Failure on the part of the attendant to keep this gap the proper size at all times resulted in the frequent extinguishing of the arc. The heat being confined to the smallest area, the expansion and contraction strains were small.

Welds made by this method were feasible for pressures of 500 lb. per sq. in. with half-inch plates, as had been demonstrated by experiment.

The metal of the weld could be controlled by the kind of metal that was added. The weld was made thicker than the original plate to be sure of strength.

There was at the present time a small water-tube boiler of the vertical two-drum type in service. All the tubes were bent and there was not a rivet in the drums.

A written discussion of Mr. Wildt's paper was presented by P. A. E. Armstrong,[1] and illustrated with lantern slides. The superiority of electric welding over gas or fire welding, Mr. Armstrong said, was due to the extremely localized character of the heat generated by the electric arc, thereby resulting in a smaller area of thermal disturbance.

While the electric carbon arc had a tendency to heat the metal almost as much as the gas process, the bare-wire electric process restricted the thermal disturbance in a large measure. The deposited metal, however, was usually oxidized and distinctly cold-short, therefore having almost a complete absence of ductility. The problem was to surround the bare wire with a substance such as the slag which formed when steel was made in order to protect the metal of the weld from the evils of oxidation. Such a means was employed in an electrode recently developed in Great Britain.

The special electrode was composed of an iron or steel core. Running parallel to its axis was a very thin aluminum wire, its purpose being to purify the melt, and covering its entire length was a braided slag. The current passed through the core. The slagged end of the electrode was brought in contact with the job to be welded and an arc formed which had the effect of fusing the core and the covering slag. The atmospheric arc was extinguished and a quasi arc of vaporous slag took place. The molten metal flowed out at the end of the electrode upon the work and was at all times covered with a large body of protecting slag, which had the effect of localiz-

[1] 61 Broadway, New York City.

ing the heat and insuring the complete fusion of all metal within its vicinity. There was no tendency for the slag to become entangled with the weld, as it was much lighter than metal and had no affinity for it.

Most conclusions about the elongation of welded specimens were erroneous, as the elongation did not occur within the weld.

Corrosion was electrolytic in character and depended upon the difference in potential of contiguous areas. Commercial iron or steel contained areas which in the presence of an electrolyte, such as moisture, were capable of forming voltaic circuits, the necessary conditions being afforded by the presence of small particles of impurities or by local conditions of strain in the metal itself.

In a welded joint, if the metal at the weld were less pure than the surrounding metal, the weld would be first attacked, and if the added metal were not homogeneous, local differences of potential in the weld itself would cause corrosion at the weld. The metal deposited by the slagged electrode was of remarkable purity and hence not so readily subject to corrosion.

John C. McCabe asked Mr. Wildt about the welding temperature of 1500 deg. fahr. which he mentioned, and how the stresses set up in the weld were eliminated. He had found the welding material varied, the per cent of elongation running from a fraction of one per cent up to the highest point, 11 per cent, and in view of the bendings or flexures that occurred in the best-formed cylinders, he failed to see how an autogenous-welded vessel, as the problem was understood, could be considered a safe one.

Was not the great difficulty with all autogeneous welding for boiler plates in general the fact that so much of the plate adjacent to the weld was heated, the elastic limit of the plate reduced and its elongation increased? asked Christopher H. Bierbaum. It was known that autogenous welds could be made that were as strong or stronger than the original metal, especially if the weld were left a little thicker than the metal itself. Under such circumstances there was no question as to the strength of the weld that could be made, but did not the internal strains and the heating of the plate induce conditions which should be very carefully determined before any theoretical conclusions could be drawn?

In his oral closure, Mr. Wildt said that the temperature of 1500 deg. fahr. was more or less estimated. He also called attention to the fact the same disturbance was set up when the process of welding approved by the Boiler Code was used as when the pencil electrode method was used. When one considered the strains due to contraction and expansion, they were very much less in the pencil method than in the approved form of welding. This was because the heat was localized and confined to a small area. In the pencil method, the weld was heated, while with the approved forged-weld process there was quite a considerable area heated along the entire length of the seam.

RAILROAD SESSION, FRIDAY MORNING

Before a representative audience, the Railroad Session of the Annual Meeting was called to order by E. B. Katte, Chairman of the Sub-Committee on Railroads, who introduced Mr. T. L. Burton. Mr. Burton presented a paper on Clasp Brakes for Heavy-Passenger-Equipment Cars. The author first discussed the braking required for present-day heavy-steel-passenger-car equipment, and then gave results of several series of brake tests made by different railroads since 1902. As the author stated in his presentation, he did not attempt to describe any particular brake, but confined his remarks to what might be expected of a clasp brake properly designed and constructed.

The discussion was opened by H. H. Vaughan, who commended the author for calling attention again to the desirability of this type of brake, which has been so clearly established by experiment and experience. He said the only reason the brake was not adopted on the Canadian Pacific Railway was that they had a type of truck to which it was difficult to apply it, and that with the low speeds there was apparently no advantage in the clasp brake over the ordinary brake with a large area of brake shoe.

S. G. Thompson also agreed with the author as to the superiority of this class of brake. He said it is perfectly reasonable to think that better results will come from applying the braking force on the two sides of the wheel.

His road had the advantage of having Mr. Burton design some of their equipment in the early days of the clasp brake, and it was under his supervision that a great deal of the preliminary detail work was done.

C. D. Young also heartily indorsed everything in Mr. Burton's paper. He said the Pennsylvania Railroad had and still has quite a large number of steel cars with four-wheel trucks with the single-shoe brake, and they had come to the conclusion that the saving of brake-shoe material would justify the reconstruction, so that as far as this road is concerned there will be nothing but clasp brakes on their steel equipment in time. The same thing applied to the six-wheel-truck cars, for which it is still more difficult to get a successful design.

He emphasized Mr. Burton's contention that for the successful and economical operation of the clasp brake the design must be correct. If you do not have a correct design you will not get the results, and he knew of installations today which were incorrect and which should be modified to get the advantages to be expected from two shoes per wheel.

He thought that some day we will see the clasp brake adapted more generally to tenders, engine trucks, where the wheels are heavily loaded, and freight cars.

A written discussion was contributed by O. C. Cromwell, who outlined the experiences of the Baltimore & Ohio Railroad with clasp brakes. This road now considers this brake the standard brake equipment for heavy-passenger-equipment cars. Mr. Cromwell's discussion will be published in full later.

In closing the discussion the author pointed out that one of the most important advantages of the clasp brake is with low-speed trains, where it reduces, if not eliminates, slack action. If there is anything second in importance to stopping trains in a desired distance it is in stopping them smoothly from low speed.

What Mr. Young said on the importance of properly fitting a brake design is another explanation for the absence of illustrations in the paper of the design. He had occasion to supervise if not to make a great many clasp-brake designs, and it is the rarest thing in the world to find one design suitable for two similar but different designs of cars. With respect to the application of the brake for heavy-equipment freight cars, he said he had just completed designs for some coal cars to carry 240,000 lb. of coal, weighing about 350,000 lb. when loaded.

MR. MUHLFELD DISCUSSES COMPREHENSIVELY THE SUBJECT OF THE USE OF PULVERIZED FUEL IN LOCOMOTIVES

In the second paper of the session, John E. Muhlfeld gave the principal facts and conclusions resulting from a number of years of investigation and research and of development work in connection with the important subject of the use of pulverized fuel in steam railway operation. Mr. Muhlfeld's paper was a comprehensive treatise covering the entire field of the subject—preparation of the fuel, storage, handling, burning, and locomotive performance. It concluded with a summary of the advantages of the use of pulverized fuel in regular road passenger and freight service and was supplemented with a number of illustrations setting forth the principal reductions to practice and results obtaining at this time.

The oral discussion of the paper was opened by W. L. Robinson, who expressed his opinion that the paper covered practically everything, although a number of points could be elaborated upon.

Mr. Robinson said that the application of powdered fuel would be a practical advantage on his own road at the present time on account of the irregularity of supply of coal and the car shortage. Using pulverized coal would do away with this entirely.

He thought the biggest thing that would appeal to the conducting-transportation side was the delays at terminals. On one of the larger roads, which uses about 6,000,000 tons of coal a year, the average mechanical delays at some of the heaviest maintaining stations are between 10 and 11 hours, and the lowest delay at dispatching stations is from $3\frac{1}{2}$ to 5 hours, or an average of 6 hr. 7 min. There is no question but what if you could eliminate the ashpit delays you could cut the delays nearly in half.

One statement of the author that impressed him was that with pulverized coal more skilled manual control of combustion and assistance to the engineer in the operation of the locomotive and observation of track and signals were secured. He thought that would help a great deal toward safety.

The chairman expressed a difference of opinion with one paragraph in the paper, that the extraordinary expenditure required for first cost and fixed charge, as well for combined maintenance and operation, together with the necessity for reliability and flexibility, preclude the general use of electricity as a motive power. He thought it would not be difficult to show that the electric locomotive, and the complete electrical installation behind it, can be maintained cheaper than the equivalent steam unit. As to reliability, he believed the electric installation has been shown to be more reliable under all conditions than the steam; and as to flexibility, in some cases two electric will replace three steam locomotives, and the electric locomotive does not have to be turned round, nor go to the ashpit, nor receive coal. He admitted that at the present time the first cost precluded the use of electricity except under special conditions.

George L. Fowler took up a point not touched on in the paper or discussion,—the action of fireboxes in service. The application of powdered fuel appealed to him very strongly from the fact that apparently with it a more constant firebox temperature could be obtained. It is very difficult to appreciate how sensitive a firebox is to slight variations in temperature.

C. D. Young gave his experiences, extending over four years, in attempting to burn powdered fuel in a stationary locomotive firebox. In his own words:

"The result of that work up to this time indicates very definite limitations in the use of pulverized fuel. The first limitation we have found is that, when we attempted to burn the quantity of fuel per hour that would justify the expense of putting the device in the locomotive, we melted up most everything that we had in the firebox. Our combustion chamber gave us trouble and annoyance that would make it impracticable for us to apply the device to road operation. This can be controlled, at least we have controlled it, but as soon as we attempt to control it we offset the efficiency of combustion; in other words, we reduce the temperature of the firebox by excess oxygen, so as to protect the fire-brick in the box, then we have excess fuel for that burning rate.

He thought it very desirable, however, that everyone who has the problem that powdered fuel presents should work upon it.

Mr. Young then took up various points in the paper and discussed them in the light of his own experience, summarizing in conclusion with the statement that the powdered-fuel stoker, operating as it does with reduced stand-by losses, gives that margin of economy to pay for the stoker.

L. S. Randolph thought that in designing the apparatus for storing and handling powdered fuel, the matter of dust explosions should be watched very closely. While the author seemed to have passed over this question with very slight reference, it should be elaborated on and handled very carefully.

To G. M. Basford, who next discussed the paper, two statements stood out above all the other good ones in this paper. The first was: "The future steam locomotive, on account of its track and bridge weight and tunnel and overhead clearance limitations, will be required to produce the maximum hauling capacity per unit of total weight." We have not yet gotten fairly started on that principle, and to have that question raised in connection with the subject of improved combustion, or pulverized fuel, really was, it seemed to him, a very important thing to come before the engineers and the railroad people at this time.

The other statement of equal importance was the comparison of the work of an Atlantic type locomotive, burning pulverized fuel, with that of a Pacific type locomotive. There are so many Atlantic type locomotives in this country to-day, and the Atlantic type of locomotive really represents in this case a large number of small engines in every part of the country. This statement becomes so important because the Atlantic type, with improved combustion, can be made to do in one case the work of a Pacific type engine, and the next thought naturally is: How many Atlantic types may be made to do the work of Pacific types today? By applying this pulverized-fuel principle to new designs, it will have the effect of prolonging the life and putting back into service a good many outclassed engines on the one hand, and introduce the possibility of using it from the ground up in new design where you start with a clean sheet of paper. That has never yet been done, with the exception of the consolidated locomotive on the Delaware & Hudson.

Charles Whiting Baker was impressed with that part of the paper wherein it was stated that the pulverized-coal equipment would permit the use of low-grade fuels. In some of the special locations where such fuels are obtainable for successful development of powdered fuel, a large reduction in operating expenses may ultimately be brought about, even when the cost of fuel is taken into account.

He thought that the possibility of using this development for switching locomotives in yard service was of immediate interest. If with powdered coal you get a locomotive free

from smoke, you have taken a big step toward putting an end to the agitation against the switching locomotive with its smoke.

It would be very desirable if the author, in his closure, would state if it were possible to regulate the burners so that the amount of fuel burned could be made to correspond with the demand for steam—whether it were possible, for example, to operate a switching locomotive and not have it blow off and waste heat while standing.

Angus Sinclair considered that the progress made lately with the combustion of pulverized fuel has been greater than any made in railway operation for many years.

A lengthy written discussion of Mr. Muhlfeld's paper was contributed by E. H. Stroud, who predicted that still better results will be had than those cited in the paper.

C. W. Corning enlarged, in a written discussion, upon some of the good qualifications of powdered-fuel burning stated in the paper.

J. H. Manning wrote that the paper ably covered the ground, and confirmed the author's statements with experiences with Engine No. 1200 on the Delaware and Hudson.

S. S. Riegel lent further assurances of eventual successful operation of powdered-fuel equipment for locomotive service by referring to important successful users of powdered fuel in industrial works. He stated that the final and best results had not yet been obtained.

In his closure, Mr. Muhlfeld discussed the question of the steam *vs.* the electric locomotive, stating as his opinion that the self-contained motive-power unit will be the one upon which we will have to depend for handling heavy freight trains over long distances. Of course, in a terminal proposition we have other conditions, and electrification is bound to be installed.

He replied to Mr. Baker's question of the applicability of powdered fuel to switching service, that one thing which has caused a great deal of trouble is the absolute control of the fuel bed. This has only been attained recently, with the development of a special feed-governing device which gives almost any range and is very effective.

THE MECHANICAL DESIGN OF ELECTRIC LOCOMOTIVES DISCUSSED BY MR. BATCHELDER

The paper by A. F. Batchelder on the Mechanical Design of Electric Locomotives dealt with features of safety of operation, general requirements of design, adaptability to service conditions in regard to nature of traffic and track, convenience of arrangement of operating devices and location of operator as affecting safety and efficiency, power efficiency as affected by mechanical design, service-time factor, cost of maintenance of permanent way and of locomotives, and first cost of a locomotive. The paper was presented by the author, who felt that too much importance could not be given to developing to the utmost the mechanical part of the electric locomotive that is the simplest in design and highest in efficiency.

C. H. Quereau presented a written discussion, which will be published in more extended form later, in which he gave statistics which would permit a personal conclusion as to the reliability in service of the electric locomotives used on the New York Central Railroad. He thought that these statistics would probably be more satisfactory than any general statement or expression of opinion, no matter how authoritative.

Experience had shown him that the cost of maintenance of engines in switching service was about twice that of those used exclusively in road service. During the period 1912-1915 the cost of maintaining the road locomotives had been about 2.5 cents per mile and that of the switch engines about 4.8 cents per mile. For the first ten months of 1916 these figures had been approximately 2 cents and 4 cents, respectively, but he doubted whether they could be kept permanently at this level. It was only fair to state in this connection, however, that the locomotives had not been designed for switching service, and with that in view they had given remarkable results.

George Gibbs, who also contributed a comprehensive written discussion which it is impossible to abstract satisfactorily, and which will therefore be published in full later, gave some opinions of his own regarding electric-locomotive design. He stated at the outset that a complete presentation of this subject has yet to be made. All we can really do at present is to chronicle experience with various types and classes of electric locomotives in various services. Unfortunately, the total number actually in service is quite limited, and the period over which our experience runs is also, in many cases, short.

He would say, generally, however, that the elimination of reciprocating parts from the locomotive—a result accomplished in electric but impossible in steam locomotives—did not warrant us in abandoning some of the very important principles well demonstrated in steam practice; namely, that for safe and successful operation under average track conditions, high center of gravity, low dead weight below spring supports and unsymmetrical wheel and weight distribution give best results. All this applied especially to high-speed operation; for low speed similar arrangements were also desirable but not so essential.

C. E. Eveleth also contributed a written discussion, in which he endorsed the paper as bringing out all the essential elements which should be taken into consideration and properly balanced before judgment is passed in favor or criticism of the mechanical features of a particular locomotive.

With the author's suggestion of the use of a truck center pin located in a well-elevated position, all of the advantages of high center of gravity, so far as effect on rail displacement was concerned, could be obtained. On the other hand, with ordinary leading-truck designs, it appeared that the high-center-of-gravity designs would give a low-center-of-gravity effect by the action of the rear truck on the track unless the high-center-pin arrangement suggested by the author was adopted on the trucks. Apparently, if high center pins were used on the trucks, the location of the center of gravity was of little importance. He referred, of course, to symmetrically designed locomotives intended to run in both directions.

He stated the incontrovertible facts upon which, from a mechanical standpoint, Mr. Batchelder's claim for superiority of the bipolar gearless design for high-speed service is found. Features which do not seem to have had general recognition place this design distinctly in a class by itself, and it is therefore to be expected that where the system of electrification will lend itself to the use of this type of engine, its application will become very general.

The chairman, opening the oral discussion, thought that it is perfectly obvious that the only difficulty in getting the electric locomotive to ride as well as the steam locomotive is the added requirement of operating in both directions, and of course this arises from the fact that the machine must necessarily be symmetrically designed about a center, or by means of cross-equalizing an effect of dissimilar ends must be created. He thought the addition of hub springs had done more towards the easy riding of a symmetrical locomotive than perhaps any other thing. The effect is, that immediately there

is an irregularity in the track, one wheel tends to rise, to leave the track, and because of the turning effect, the tendency is to skew that axle. Because of the very sensitive springs on the top of the wheel, the wheel is almost immediately forced back to the track, and the tendency to oscillate has been broken up.

This was very noticeable on one of the late types of New York Central engines. Before the springs were added, it was possible, when running 60 or 65 miles an hour, to see the equalizers work, but after the application of hub springs, the equalizers acted so quickly that the eye could not follow them. He had always believed that it was the application of these hub springs that created the particularly easy riding of the late type of New York Central locomotives.

L. S. Randolph took up the question of the guiding action of trucks, which he thought would repay study, especially in connection with the electric locomotive.

The safety of operation was next discussed, and George L. Fowler questioned the author's statements. This discussor gave results of his investigations in regard to the lateral thrust of engines and cars upon the track. He gave diagrams on the blackboard to show why he disagreed with the author's statement that the rear driver puts an excess pressure on the rail on the outside above the other wheels. He also demonstrated by diagrams what thrust is put on the track on a curve by the wheels of various types of engines.

As to the effect of height of the center of gravity, Mr. Fowler gave his reasons for thinking that the thrust is quite as dependent upon the character of the wheel and that of the vehicle as it is upon the center of gravity. In making some investigations in which he had occasion to measure the thrust on trains running from 50 to 60 m.p.h. over an 8-deg. curve, track elevated for a speed of 24 m.p.h., he found that the locomotive did not begin to put the thrust on the rail that a sleeping car at the back end of the train did, and yet the height of the center of gravity of the locomotive and that of the sleeping car only varied about three or four inches.

Mr. Batchelder, in his closure, pointed out that one question he wanted to bring out was the desirability of having more weight on the rail at the place of the thrust. That place, by actual test, is at the rear truck. That is not from guesswork, or from theory, or from calculation, but is actual fact, tested and observed for 50,000 miles of running, for the particular purpose of finding out where the double-end locomotive took its thrust. He had witnessed rails displaced ¾ in. when the front end of the locomotive was on the track.

Mr. Fowler asked Mr. Batchelder if that were not on tangent track, and he replied that it was.

Mr. Batchelder continued that in striking a curve, running on a tangent track, you are oscillating. All the locomotives he had seen run did; if it is a tangent track they are working from side to side, providing you haven't got a "cock-eyed" truck. When the forward truck gets to one rail or the other, it hits the rail, and there is only one place to hit it, and that is at the rear end.

On a curve he had never seen any trouble with double ends, except where a large resistance was put against the curve, the trucks, in other words, putting on too much resistance. A double-end engine, according to his experience, is absolutely smooth and good running on a properly elevated curve.

In regard to Mr. Quereau's remarks as to the pivot point of the leading truck, he had to say that he knew no way of observing it, but in his opinion the outer rail would be the point of pivoting. The same discussor had spoken about the resistance tending to prevent the guiding trucks from oscillating, and he believed that this was true. With the engines the discussor had in mind there was a frictional resistance, and when once the truck had taken a position, something had to be struck before it came back into another position, and it might therefore run cock-eyed on the track and cause flange wear, and in that particular case flange wear was much preferable to oscillation.

Mr. Katte had spoken of coil springs on the box, and he would add that his experience with them had been gratifying.

Mr. Young had understood him to say that a locomotive would not run backward safely. He would rather modify that statement and say that it was not desirable to run it backwards. For that matter, he did not know of any operation of locomotives at 80 m.p.h. backwards, especially of the American type. However, in making tests of two American-type locomotives back to back, with leading trucks, it had been his experience that those locomotives, when run at as high a speed as 80 miles, did affect the track and sometimes very seriously. The defects were not immediately apparent, but they developed sooner or later.

WORK OF THE BOILER CODE COMMITTEE

THE Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York City.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply, is then prepared by the Committee and passed upon at a regular meeting of the Committee. This interpretation is later submitted to the Council of the Society for approval, after which it is issued to the inquirer and simultaneously published in The Journal, in order that any one interested may readily secure the latest information concerning the interpretation.

Below are given the interpretations of the Committee as approved by the Council on December 7, 1916, in Cases Nos. 87, 113-123 inclusive. In this report, as previously, the names of inquirers have been omitted.

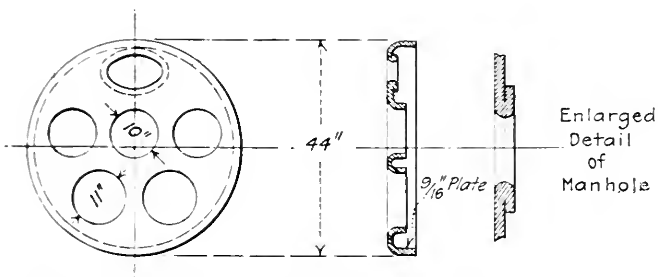

Fig. 6 Special Construction of Manhole Opening

Case No. 87

Inquiry: Is there any restriction in the Boiler Code against the purchase of steel plate by weight per square foot instead of by gage, provided there is a factor of safety of five throughout?

Reply: The Boiler Code does not specify how the plate shall be bought, but material must comply with the Code specifications.

Case No. 113

Inquiry: *a* Are the furnace sheets in all water-leg boilers, such as vertical fire-tube boilers, to receive staying as flat plates; that is, when it is necessary to use staybolts on a circular furnace sheet, is no value to be given according to the Code, to the furnace sheet due to its curvature?

b When the circumferential and longitudinal pitches are not equal, can their product be used in place of p^2, in Par. 199? Also, can it be used and made equal to the square of the values given in Table 3?

c Is it the purpose of Par. 207 to provide a greater spacing than shown in Table 3 for flat plates?

d Is Par. 257 intended to do away with the bevel shear for finishing the calking edges of plates, and does it mean that the plate edges may only be planed, milled, or chipped?

Reply: *a* An internal cylindrical furnace which requires staying, shall be stayed as a flat surface, and no value will be given the furnace sheet due to its curvature, in accord with Par. 212. (See also the Reply in Case No. 57.)

b No, *p* must be measured as specified in Par. 199.

c Par. 207 was not intended to cover the spacing of staybolts on flat plates, but was intended for staybolted surfaces where some form of reinforcement is applied.

d According to Par. 257 of the Code, in order to eliminate the incipient cracks left by shearing, the edges of the plates must be finished by planing, milling, or chipping, whether they are sheared straight or beveled.

Case No. 114

Inquiry: Is it allowable under Par. 333 of the Code to stamp a locomotive type boiler over the fire door, when the latter is located in the side of the furnace section of the boiler?

Reply: Such a boiler may be considered a special type, and according to Par. 333j, the stamp shall be placed in a conspicuous location. It is therefore correct to place the stamp near the fire door.

Case No. 115

Inquiry: Is it permissible under the Boiler Code to use manhole openings in the heads of boilers constructed as shown in Fig. 6?

Reply: Yes, when the head is flat and stayed with tubes as shown in the sketch, or otherwise stayed.

Case No. 116
(In the hands of the Committee)

Case No. 117
(Annulled)

Case No. 118

Inquiry: Is it permissible under Par. 185 of the Boiler Code, to build a horizontal return tubular boiler of 19/32-in. plate (1/32 in. heavier than the limit placed by Par. 185) without planing down the circumferential joints?

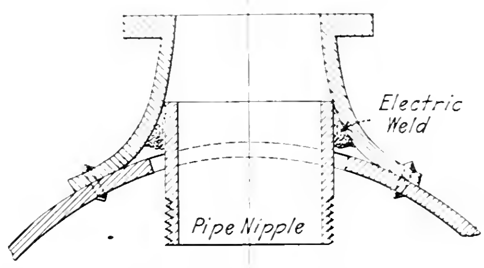

Fig. 7 Welded Connection for Internal Pipe to Nozzle

Reply: The shell plates in horizontal return tubular boilers, where the plate thickness exceeds 9/16 in., must be planed down at that portion of the circumferential joint exposed to the fire or products of combustion, as required under Par. 185 of the Boiler Code.

Case No. 119

Inquiry: *a* Is it permissible under Par. 274 of the Boiler Code, for a pop safety valve with a higher lift than the maximum given in Table 8 of the Code, to use the manufacturers' rated capacity of discharge?

b Under Par. 421 of the Code, is it permissible to rate discharge capacities of safety valves proportional to the lifts, when the lifts exceed the maximum given in Table 8 of the Code?

c If for a boiler equipped with a superheater, one 3-in. or smaller safety valve provides sufficient relieving capacity, is it necessary to place a safety valve on the superheater outlet in addition to that on the boiler, or will one safety valve on the superheater outlet be sufficient for both superheater and boiler?

Reply: a According to Par. 274 of the Code, if the marked relieving capacity of the valve exceeds that given in Table 8 of the Code, the maximum relieving capacity given in Table 8 governs in determining the minimum capacity of safety valve or valves to be placed on a boiler. It will be noted that the capacities given in the Table are for bevel-seated valves; for flat-seat valves, increase these values by 40 per cent.

b In determining the minimum capacity of safety valve or valves to be placed on a boiler, the Table should be used in accordance with Par. 274.

c According to Pars. 269 and 288 of the Boiler Code, one safety valve will be sufficient for both superheater and boiler, provided one 3-in. size or smaller safety valve will meet the requirements for the minimum capacity of safety valve or valves to be provided. For greater relieving capacities than this the Code calls for two or more safety valves.

In view of the resistance to the flow of steam through certain forms of superheaters, recommendation has been made to the Committee that the Code be revised after the Public Hearing on December 8-9, to specify the use of both superheated and saturated valves, without exception, in all superheater boilers.

Case No. 120

Inquiry: Is it to be understood, under Par. 18 of the Boiler Code, that in order to obtain the required thickness of the shell and dome plate after flanging, that sufficiently heavier plate must be used to give the required thickness at the edges after the flanging process?

Reply: According to Par. 18 of the Code, the minimum thickness of shell plates and dome plates after flanging, must be 5/16 in. for diameters of shell from 36 in. up to and including 54 in. in diameter.

Case No. 121

Inquiry: Is it permissible under the rules of the Boiler Code to make a joint by welding a coupling or nipple by the autogenous process to the underside of a steel flanged feed connection?

Reply: If the coupling or nipple connection is securely fastened to the inner side of the steel flange feed connection by the welding process, the requirements of Par. 315 will be complied with.

Case No. 122

Inquiry: Is it permissible under the rules of the Boiler Code to weld to the inner side of a wrought steel steam nozzle a coupling or nipple connection for a dry pipe within the boiler, as shown in Fig. 7?

Reply: There is nothing in the Code to prevent the use of autogenous welding for this joint where no strain is brought on the joint through the action of the steam pressure.

Case No. 123

Inquiry: If a boiler is so designed that a manhole applied as required by Par. 264 cannot be used for cleaning and inspecting the boiler, would the requirements of this paragraph be met?

Reply: In requiring manholes for boilers, as specified under Par. 264 of the Code, it was the intention that the boiler should be so designed that the manhole would be serviceable for entering the boilers for cleaning and inspection, and all such boilers as referred to in that paragraph should be designed so as to accomplish this purpose.

SOCIETY AFFAIRS

A Record of the Current Activities of the Society, its Members, Council, Committees, Sections and Student Branches; and an Account of Professional Affairs of Interest to the Membership

ELSEWHERE in this number will be found the account of the Annual Meeting. Those who were obliged to miss this convention lost an event. In order for one to progress in his work it is essential to keep in touch with the outside world and these occasions where members of the profession from every section of the country get together are an inspiration to all.

The spirit of mutual helpfulness and coöperation was especially prominent. The keynote was sounded by our Dr. Hollis in his remarks on accepting the presidency for 1917.

Dr. Hollis's speech presages a remarkable year for this Society, and it is fair to assume that other societies are similarly imbued with the sense of their obligation and opportunity.

I took breakfast on two occasions in the week of December 11 with His Excellency, Nicholas P. Melnikoff, the engineer member of the Cabinet of the Czar of Russia.

His Excellency is just completing a tour of the United States to learn American methods and to obtain information generally for the development of Russia, including such a variety of subjects as: methods of gold dredging, lumbering, brazing, smelting, lighting of cities and district steam heating.

He informed me of opportunities of the most fascinating character, for instance, there is one million water horse-power capacity of development within seventy-five miles of Petrograd. Should American enterprise see fit to at once request concessions they would be favorably granted, whereas after the war no one nation could be thus favored.

In addition to this opportunity of the Society to serve the official representative of a nation in securing information of the widest scope for its future development, I was impressed with the fact that there is an engineer in the Cabinet of the Czar. There is no such cabinet officer in the United States. We have no officer representing industry, in distinction from one representing labor and commerce.

This is the greatest industrial nation on the globe and the relation of the engineer to industry is so intimate that perhaps it is not an extravagant hope that during the progress of our country there may be a department of engineering sometime created in the Cabinet of the President of the United States.

The office of Engineer of the Imperial Cabinet, in Russia, while it did not always have this name, is an extremely old one. As early as the fifteenth century John the Terrible attached to his household engineers whom he brought over from Greece to build the Cathedral of St. Basil. Peter the Great at the beginning of the eighteenth century similarly established engineers with official titles as his personal advisers, and moreover made them his personal friends in much the same way that the President of the United States does his physician.

The Engineer of the Russian Imperial Cabinet has a great range of duties. He is the adviser of the Emperor in not only the technical matters pertaining to his palaces but to the cities known as palace cities, that is, the towns in which the imperial palaces are located, and the entire administration, including the police, is in the hands of the palace authorities.

By virtue of the fact that the imperial domains embrace vast territories, larger even than France, not only in the vicinity of Petrograd but in Turkestan and Central Asia, the Engineer is responsible for the development in forestry, lumber, irrigation, agriculture, mining, etc., and it is for these vast sections having untold wealth and resources that His Excellency invites the interest of American enterprise and capital. He told me that he would personally assist any desiring to investigate these opportunities.

With the extraordinary development of the chemical industry in this country and the happy bringing together of the American Chemical Society in intimate coöperation with the Engineering Societies by the recent invitation of the President of the United States, it has occurred to the Secretary to suggest to the members that they observe the remarkable opportunity of the mechanical engineer in chemical industry. Such work as we might undertake is peculiarly ours as distinct from other branches and obviously distinct from chemical work as such, namely, the transfer of a perfected laboratory process to a manufacturing process including plant layout, the handling of materials to secure the most efficient routing, the designing of machinery to get the best results, etc.

With the experience of the nations now at war who are working in mass production for the first time in their history, these nations will henceforth be able to supply to still better advantage all of the materials which they have been accustomed to supply.

In Canada, so I am informed, apropos of competition in manufacture, any individual in the Dominion may go into any factory making munitions and observe the processes and go out and compete. No secrecy is permitted, as this would defeat the object of defense of the Dominion.

What has been made a necessity in Canada by virtue of the war, in its fundamentals will hold as sound business policy in times of peace.

In general there is throughout the country the greatest freedom of visitation in our industries. In ten years, with quite general extension of courtesies to foreign visitors with letters of introduction through our various manufacturing establishments, only one in the whole United States has refused admittance to such a visitor when duly accredited by this Society.

What we need is the actual getting together in conference of the various heads of competing industries for the purpose of comparing costs, developing the most up to date methods for execution in the several plants on much the same basis that a consultation of management of several companies under one administration would naturally effect, so that we obtain all the benefits of wholesome rivalry in manufacture, reducing costs without loss of independence. Then the different industrial organizations should again get together in a coöperative work of selling the American product.

The part of the engineer in all of this is that he should participate in all such conferences. The more an engineer takes a national and even a world view point the more service is he to his profession. CALVIN W. RICE, *Secretary.*

ANNUAL BUSINESS MEETING

THE annual business meeting of the Society was held in the Auditorium of the Engineering Societies Building on Wednesday, December 6th, 1916, at 10 a. m., in connection with the 37th Annual Meeting. Dr. D. S. Jacobus presided.

The Secretary presented the Annual Report of the Council for the year 1916, to which was appended the Reports of the Standing and Special Committees. This report will be published in full in Volume 38 of the Transactions of the Society, and is here given in abstract only. The Reports of Standing Committees were published in The Journal December 1916.

Abstract of Council Report

The Council has held eight monthly meetings and two special meetings, and the Executive Committee of the Council has met five times between meetings of the Council.

The Council registers with deep regret the deaths of E. D. Leavitt, and John E. Sweet, both Honorary Members and Past-Presidents of the Society. Special commemorative resolutions were passed by the Council.

Dr. Ambrose Swasey was this year elected an Honorary Member.

While this year in the affairs of the Society has been one of increased internal activities proportionate to the growth in membership and standing of the organization, and increased inter-society coöperation in matters affecting the Engineering Profession as such, the most significant development of the year has been the Society's participation in movements for the national service. In common with the other national engineering societies, our Society has been called upon by the Government to perform work for the public welfare, and, in turn, we as engineers have received recognition in legislation directly and permanently establishing our profession as an arm of the Government.

Before reviewing the conspicuous and important phases of the activities during 1916 of the membership, committees, sections and student branches, and enumerating the actions taken in joint society matters, this report first refers to the relations the Society has maintained in its service to the nation.

INDUSTRIAL CENSUS

Last year national recognition was accorded the Engineering Profession in the invitation extended to the engineering societies by the Secretary of the Navy of the United States to nominate the members of a Naval Consulting Board. This Society's representatives on the Board are Spencer Miller, Member of the Council, and W. L. R. Emmet.

To conduct the work of compiling this inventory, a Committee on Industrial Preparedness, a sub-committee of the Naval Consulting Board, was constituted with Howard E. Coffin, Mem.Am.Soc.M.E., as Chairman.

To assist this committee in its work, State Directors were appointed, one in each State for each of the national societies mentioned in President Wilson's letter, and they in turn have been generously assisted by "field aides" composed of other members of the Societies who in many cases personally visited the different plants in order to secure the required information.

The Council records its appreciation of the work of the Society's representatives in this splendid movement, which has now been carried through with complete success.

ENGINEER CORPS AND NATIONAL COUNCIL OF SAFETY

In response to an invitation from General Wood, Commander of the Department of the East, a joint committee was chosen by five national engineering societies to facilitate the carrying out of the organization of a Civilian Engineer Reserve Corps as a part of the military forces of the United States. This committee organized with an executive committee of: Wm. Barclay Parsons, *chairman;* H. S. Drinker, Wm. H. Wiley, B. J. Arnold, Ralph D. Mershon. The committee made its first report in December 1915, and in July 1916, Chief of Engineers, Lieut.-Col. E. Eveleth Winslow of the Army Engineer Corps, in writing to all the engineer officers throughout the country said, "Congress has now provided a means by which the civilian engineers can more than fully prepare themselves for that highest duty of citizens—the defense of our country." The bill became effective on July 1, 1916, thus directly and permanently establishing the Engineering Profession as an arm of the Government. Public recognition of the engineer is now as accomplished fact.

As a sequel to the work of the Naval Consulting Board, a bill has been passed by Congress providing for a National Council of Safety, consisting of five Cabinet officers and not more than seven civilians. The latter will be chosen, one each, to represent labor, industry, finance, transportation, physics, chemistry and commerce.

STANDING, ANNUAL AND SPECIAL COMMITTEES
STANDING COMMITTEES

Finance Committee. Last year, when a serious business depression in this country seemed imminent, precautionary measures were taken to conserve the interests of the members of the Society in every proper way. This conservation was carried out a little more than later proved necessary, although not more than seemed wise at the beginning of the year, with the result that we saved $24,000 to go into the surplus. This is made available to increase our working capital, a necessity by virtue of the Society's rapid growth.

All the gifts of money to the Society are intact and invested, and initiation fees have been used during the last few years to retire the certificates of indebtedness issued to pay off our share in the land of the Engineering Societies Building. Our sister societies were each able to pay off, by subscription, their individual share—$180,000—of the purchase price of this land, but with our subscriptions amounting to only about two-thirds of the gifts received by these societies, we have been able to finance the problem on another basis; yet we were the first to pay off the mortgage on the land, by means of certificates issued to the membership. Our certificates were retired on July 1, 1916.

Meetings Committee. The culmination of the work of this committee is represented in the Thirty-sixth Annual Meeting held in New York in December, 1915, and the spring meeting held in New Orleans in April, 1916. Too much praise cannot be accorded to the members of the committee for the great amount of time and work they have given to reviewing manuscripts of the papers presented and arranging the programs of these meetings.

The committee has received valuable assistance in its work from its sub-committees on Air Machinery, Cement Manufacture, Fire Protection, Gas Power, Hoisting and Conveying,

Industrial Buildings, Machine Shop Practice, Protection of Industrial Workers, Railroads and Textiles.

THE ANNUAL MEETING

The Thirty-sixth Annual Meeting was held in New York City, December 7-10, 1915, inclusive. Enthusiasm was manifested in various ways: there was a series of conferences of representatives of the Sections, at which "Extend the Local Sections" was distinctly emphasized; at the Council meetings the sentiment expressed was equally enthusiastic; the spirit of democratization was dominant, and the membership was encouraged to participate in the affairs of the Society to a greater extent.

Unusually valuable contributions to the professional program were made by several of the sub-committees of the Committee on Meetings, and by local committees. At this particular meeting, seven papers were contributed by Sections and thirteen, including reports, by sub-committees.

The papers presented were representative of the mechanical engineering work of the country as a whole, having been selected through intimate acquaintance with the subjects to be discussed and on the mature judgment of the expert engineers who constitute the different sub-committees.

THE SPRING MEETING

The Spring Meeting was held in New Orleans, April 1 to 14, 1916. The local membership of the Society, the association of local members of the American Society of Civil Engineers and the Louisiana Engineering Society, acted jointly as hosts.

Special cars were run from New York and Chicago, stopping for a day at Birmingham, where the visitors were lavishly entertained by the newly-formed section of the Society in that city.

The papers presented were all of a high order, there was a large amount of discussion, and the keynote session of the meeting, on the subject of Industrial Preparedness, aroused a great deal of interest and called forth contributions from engineers from every section of the country.

Publication Committee. The publications of the year have been The Journal, which has been issued monthly, the annual volume of Transactions, the Year Book, the sixth annual volume of Condensed Catalogues, and the Power Test Code (reprinted from vol. 36 of Transactions).

Plans are under way for the further development of The Journal to include such features as will, it is hoped, make this publication a professional necessity to every mechanical engineer.

Volume 36 of Transactions, issued during the summer, was the largest ever published by the Society and contained nearly 1600 pages.

Membership Committee. There were 1879 candidates for membership, 1143 of whom were recommended for acceptance.

Library Committee. The principal matter of interest to the Board this year has been the consideration of the plans for receiving the library of the American Society of Civil Engineers. With this library added to that of the original Founder Societies, the largest and most complete engineering library in the world will be at the service of every engineer in whatever branch of the profession.

House Committee. The House Committee has considered the alterations required in the rooms of the Society to take care of the supporting columns passing up through the rooms to carry the load of the three stories being added to the building for additional library accommodations and headquarters for the American Society of Civil Engineers. They have also advantageously placed the insurance of the property of the Society after exhaustive investigation; have most painstakingly looked after all other interests of the Society's rooms and property, and arranged the details of the President's reception at the annual meetings.

Research Committee. The work of the Research Committee has consisted in lining up definite duties and plans for sub-committee work. The committee has now several sub-committees, including Bearing Metals, Clinkering of Coal, Flow Meters, Fuel Oils, Lubrication, Cutting Action of Machine Tools, Materials of Electrical Engineering, Safety Valves, and Worm Gearing.

Public Relations Committee. The Council has under careful consideration the entire field of the Society's activities in their relation to the public, so that no active work has been taken by the Committee this year.

Constitution and By-Laws. The Committee on Constitution and By-Laws acts in an advisory relation to the Council in consideration of suggested and necessary amendments to the Constitution, By-Laws and Rules.

Standardization Committee. This committee became a standing committee of the Society by amendment to the Constitution in the spring of 1915. The action was the result of a report prepared by Mr. Henry Hess, and approved by the Council in December, 1913. The purport of the report is that the Committee shall standardize the method of making and arriving at standards rather than create standards themselves.

NOMINATING COMMITTEE

The Nominating Committee this year was appointed by the President in a way to secure the greatest possible democracy in selecting nominees for executive offices. The Sections of the Society were divided into five geographical groups and one member of the committee was chosen from each group.

The President appointed as Tellers of Elections for 1916: Robert H. Kirk, *Chairman;* Erwin S. Cooley, Harry A. Hey.

Here follows a detailed account of the work of the various special committees for the year, and of the Society's numerous activities in coöperating with other organizations, both by joint committee work and by Society representation.

Filter Report

The Report of the Committee on Recommended Practice for Standardization of Filters was presented by George W. Fuller, Chairman of the Committee. The report outlined in a comprehensive manner the present practice in the field of mechanical filtration and emphasized the need and value of a pronouncement upon the subject of the rating of mechanical filters. It concluded with recommendations on form of expressing capacity, care as to maximum demand, depth of filter bed, normal filtering material, special filtering material, rate of filtration, etc. The report will be published in full later.

Awards of Prizes

The next business was the awarding of the Junior and Student prizes for papers presented by Junior and Student members respectively. On the recommendation of the Prize

Committees, the Junior Prize for 1916 was awarded to L. B. McMillan, for his paper entitled The Heat Insulating Properties of Commercial Steam-Pipe Coverings. Honorable mention was awarded to Victor J. Azbe for his paper on Power Plant Efficiency, and Herbert B. Reynolds for his paper on the Flow of Air and Steam through Orifices.

Student Prizes for 1916 were awarded to: Boynton M. Green, Leland Stanford University, for his paper on Bearing Lubrication; Howard E. Stevens, Rensselaer Polytechnic Institute, for his paper on An Investigation of the Dynamic Pressure on Submerged Flat Plates, and M. Adam, Louisiana State University, for his paper on The Adaptability of the Internal Combustion Engine to Sugar Factories and Estates.

Honorable Mention was awarded to: M. Boyd Gordon, University of Cincinnati, for his paper on A New Type of Unaflow Engine; S. C. Williams, Stevens Institute of Technology, for his paper on Photostatic Reproduction, and Charles P. Miller, Pennsylvania State College, for his paper on Investigation of Properties of Low and Medium Carbon Steels.

IRA NELSON HOLLIS

Ira Nelson Hollis, President of the Society for 1917, was born in Mooresville, Indiana, March 7, 1856. In 1872 he was graduated from the Louisville, Kentucky, High School, and went as apprentice in a machine shop for building and repairing all kinds of engines, particularly those for the Ohio River steamboats. His health was not equal to the work, however, and he secured an office position with a railroad company, and later with a cotton commission house in Memphis, Tennessee.

In 1874 he entered the Naval Academy as a cadet-engineer, having taken a competitive examination along with about one hundred and twenty-five others, twenty-five of whom were appointed.

Hollis stood first on the list of those who entered, and retained this position throughout the course. When it is mentioned that in the class were included such brilliant men as the late Professor Spangler, Dr. Cooley, and Admiral Griffin, the present Engineer-in-Chief of the Navy, it will be seen that this record means a great deal. There had been a separate class for engineers, of a tentative character, for some years before, but the class which entered in 1874 was the first one to follow a four years' course and pursue studies of a general character as well as those relating particularly to engineering.

It is worth noting that when this class of young engineers went through Annapolis it was before the days of thoroughly organized technical schools and first-class textbooks, with the result that the instructors in professional subjects had little to guide them in the way of successful practice in technical education elsewhere, and had to shape the course largely in accordance with their own ideas of what was necessary, supplementing such textbooks as were available with lectures based on their own experience. Several members of the Society were among these early instructors, including Captain Charles H. Manning and the late Chief Engineers, John C. Kafer and David P. Jones, all of whom have always held an extremely high place in the affection of the young men who were fortunate enough to be students under them.

At that time the unfortunate contention between the Line and Staff of the navy was still quite strong, and its influence was felt even among the cadets. The engineers were made to feel in many ways that their status, actual and prospective, was distinctly inferior to that of their confreres of the Line. The four years' association as fellow students, and in the same classes, with the exception of strictly professional work, did much toward breaking down the ill-feeling. This had so far died out that the Personnel Board in 1897, composed of Line officers and engineers, was able to agree on a union of the Engineer Corps with the Line, and their recommendations to this effect became a law in 1899.

As a rule, it is best not to stir up old troubles, but we could not fully appreciate the stuff that was in these young engineers if we did not realize that these beginners of a new régime were in a difficult position, and that they acquitted themselves most creditably. In justice to the instructors, who were almost entirely Line officers, it ought to be said that very few of them showed any partiality; that their feeling toward the engineers was in the mass, and that individuals usually received the consideration and credit which was due them.

After graduation from Annapolis in 1878, Dr. Hollis spent three years in the Mediterranean and North Sea and on the coast of Africa in the Cruiser Quinnebaug. During his time in the navy he served also on the United States Steamships Alert, Hartford, Richmond, and the Flagship Charleston.

At the conclusion of the cruise on the Quinnebaug, and after promotion to the grade of Assistant Engineer, he was detailed as Professor of Marine Engineering at Union College, Schenectady, New York, in accordance with the provisions of an Act of Congress permitting such details in order to promote technical education. This experience at Union College was excellent preparation for what afterward proved to be his life work.

In 1884 he served with the Advisory Board that built the four ships of the White Squadron, and spent some months in the inspection of machinery at Chester, New York, and Nashua, New Hampshire. On the west coast he spent three years at the Union Iron Works, where some of the early ships for the new navy were then building, among them the Charleston, San Francisco, Monterey, and Olympia. This was a splendid opportunity for a brilliant young engineer like Hollis, as giving a thorough familiarity with the very latest types of machinery, and also for contact with some exceedingly able engineers, among whom were Mr. George W. Dickie, of our Society, who was then Chief Engineer of the Union Iron Works. Everybody was full of enthusiasm, and the daily lunch table offered a forum for the thorough discussion of the many new and interesting problems which were being solved. Dr. Hollis has often spoken of the pleasure and profit of these discussions.

His responsibility was chiefly for the machinery of the Charleston, and when that vessel was completed he went to sea in her. At the Union Iron Works he had supervised the design and construction of the machinery, and now had the opportunity of seeing how it worked in practice, and to note opportunities for improvement. While on the Charleston he was detailed at Iquiqui to the Filibuster Itata after the capture for the purpose of getting her ready for a return to the United States. He went North in her in the spring of 1891, and then went to China in the Charleston. In January, 1892, he went to Newport on the Staff of the Apprentice School on Coasters Island.

Shortly before his three years of service on the Charleston would have expired, Admiral Melville, who was the Engineer-in-Chief of the Navy, was asked to designate an officer to lecture on naval engineering at the Naval War College. As it was the first time the invitation had been extended, the Admiral felt it necessary to choose a man specially fitted for this work. After a survey of the available officers, he selected Hollis, who was ordered to the Navy Department shortly before the time for the lectures so that he might prepare them. He was peculiarly fitted for this duty by his ability as an engineer, his recent experience in the building and operation of the most modern machinery, his experience as a teacher at Union College, and his felicity as a writer and speaker. The opportunity was a fine one, because no lectures of this sort had been given at the War College previously, so that he had the whole field to draw upon. The result was exactly what his friends had anticipated, and proved the wisdom of Admiral Melville's selection. The lectures were a great success in every way, and not only aroused the admiration of the officers to whom they were delivered, but were published and served for some time as a sort of textbook on modern marine machinery.

When Hollis was ordered to the Bureau of Steam Engineering, it was not alone to prepare the lectures, but Admiral Melville had selected him to be the successor of Chief Engineer (now Admiral) Frank H. Bailey as chief designer. He was Mr. Bailey's assistant, and it is safe to say that two abler designers of marine machinery could not have been found. During this service, which lasted only about a year, Hollis suggested a number of excellent features which were incorporated in the machinery designs of that period. His last work in the navy was the preparation of specifications for the machinery of the gun-boat Nashville and the design of machinery for some of the torpedo boats.

In 1893 Harvard University was looking for a professor of engineering and wished to consider, among others, a naval engineer. The high standing of Dr. Hollis at the Naval Academy, his splendid practical record, and his famous lectures at the War College, all marked him as the man to be considered. At the suggestion of the Secretary of the Navy, on the recommendation of Rear-Admiral Sampson and Rear-Admiral Melville, he was invited to accept the Chair of Engineering, and resigned from the Navy in September, 1893, to enter on his duties at Harvard University.

At that time engineering in Harvard was at a low ebb, but as a result of the endowment for engineering by the McKay fund, it was desired completely to reorganize the engineering department and form new classes in civil, electrical, and mechanical engineering. This not only called for executive ability of the highest order, but from the fact that Mr. McKay made his money in mechanical engineering, or things connected with mechanical engineering, it was desired to select a mechanical engineer to carry out the plans for development.

At the end of two years at Harvard, Dr. Hollis was made a member of the Athletic Committee and soon after became chairman. The outdoor athletics were transferred from the old home field to what is now known as Soldiers' Field, which at that time was largely a swamp. It was recovered by dredging gravel out of the Charles River and pumping it onto the swamp. While he was chairman of the Athletic Committee, Soldiers' Field was thus made into a playground, a metropolitan driveway was put along the river, a fence was built around the field and the necessary buildings connected with athletics erected, including the Harvard stadium and boathouse.

The necessity for replacing the old wooden seats on Soldiers' Field was emphasized by a fire which burned down one of the stands during a baseball game. Fortunately the excellent management, through the students, prevented injuries, but the University then took up seriously the replacement of the wooden stands by something less inflammable. Concrete, the use of which was then novel for large structures, was adopted as the most rapid form of construction, and the stadium was built in four months, to seat about 30,000 people. The thought in connection with the size of the stadium was to limit the number of spectators to that which would include only the students and graduates and their friends, as there was no thought of making a public spectacle out of athletics. The stadium was paid for in part by money saved from the gate receipts and in part by the graduates of the Class of 1879.

Under the direction of the engineering department Pierce Hall was built for the different branches of engineering. The civil, electrical and mechanical engineering departments were transferred to the building about 14 years ago, and the instruction and courses were once more reorganized.

Up to that time Dr. Hollis was Chairman of the Committee that raised the money for the Harvard Union, and it was under his supervision that its building was constructed. In this, as well as in the designing of the stadium and in other ways, he was for years intimately associated with Charles McKim of McKim, Mead & White. In every way he entered into the University life at Harvard, apart from the engineering side, and it has been reported on good authority that President Eliot said a few years after Dr. Hollis became a member of the Harvard faculty that he was the "greatest find" in 25 years.

In the discussions relative to an understanding between Harvard University and the Massachusetts Institute of Technology, Dr. Hollis advocated effective coöperation between the two, and has always believed that it would have been wrong to erect engineering laboratories in both places.

In the summer of 1913 Dr. Hollis resigned to take the presidency of the Worcester Polytechnic Institute, where there are splendid opportunities for continuing his forceful work for the advancement of engineering education.

Dr. Hollis has always retained his keen interest in the Navy, and was a very active factor in causing the Personnel Board to be organized. He was a friend of Colonel Roosevelt, who was then Assistant Secretary of the Navy, and had discussed the project of the amalgamation of the Line and the Engineering Corps with him very effectively.

The late Francis H. Wilson, then a Congressman from Brooklyn, had also discussed this same subject with Mr. Roosevelt. The result was that Mr. Roosevelt was convinced of the importance of a careful investigation of the subject, which led him to recommend the organization of the Personnel Board; and when the project for amalgamation came up it found him already posted on the subject.

Recently, Dr. Hollis had served in connection with the work in Industrial Preparedness, and just before that with the Chamber of Commerce in Washington. He was also a member of the Commission on National Defence, and its recommendations were submitted to the various chambers of commerce in the United States looking to a better Navy, a better Army and a legalized Council on National Defence. The chambers of commerce approved almost without division, and the report of the Committee and its findings have since practically been adopted by Congress.

W. M. McF.

COUNCIL NOTES

DECEMBER 5, 1916

At the meeting of the Council on December 5, 1916, the following members were present, President D. S. Jacobus presiding: John H. Barr, R. M. Dixon, *Chairman Finance Committee*, Arthur M. Greene, Jr., James Hartness, F. R. Hutton, W. B. Jackson, Spencer Miller, H. de B. Parsons, James E. Sague, Jesse M. Smith, S. T. Wellman, E. H. Whitlock; by invitation, Dr. Ira N. Hollis, C. H. Benjamin, officers-elect, W. L. Saunders, Past-President of the American Institute of Mining Engineers; and Calvin W. Rice, *Secretary*.

Sections. W. G. Starkweather was appointed on the Boston Local Committee.

W. H. Insley, Chairman, L. M. Wainwright, Vice-Chairman, W. A. Hanley, Secretary, B. G. Mering, Treasurer, L. W. Wallace and F. C. Wagner were appointed as the executive committee of the newly-constituted Indianapolis Section.

A. L. Black and A. M. Lockett were appointed on the New Orleans Committee in place of Professors Kerr and Rugan.

C. A. Paulsmeier and E. A. Rogers were appointed on the San Francisco Local Committee.

M. E. Cooley, Chairman, E. C. Fisher, T. H. Hinchman, G. W. Bissell and J. W. Parker, Secretary, were appointed an Executive Committee of the Detroit Section.

A Section at Baltimore, Md., to include all the members of the Society within thirty miles of the City Hall, was approved.

A Section at Erie, Pa., to include all members of the Society within a radius of thirty miles of the Erie City Hall, was also approved. This Section was granted the privilege of coöperating with the Engineers Society of Northwestern Pennsylvania. J. E. Wadsworth, Chairman, C. S. Hopper, Vice-Chairman, M. E. Smith, Secretary, R. Conrader, Treasurer, and N. A. Newton were appointed an Executive Committee of the new Section.

The report of the Committee on Sections, covering the work of this committee for 1916, was received and referred to the Publication Committee for publication in The Journal; it appears elsewhere in this issue.

The Council expressed its regret that the term of office of Mr. E. H. Whitlock, both as a member of the Council and as Chairman of the Committee on Sections, would expire with this meeting, Mr. Whitlock having carried the responsibilities of the organization of sections to such a splendid success. A vote of sincere thanks was accorded Mr. Whitlock and the members of his committee.

DECEMBER 8, 1916

At the meeting of the Council on December 8, the new officers were formerly introduced. The following were present: C. H. Benjamin, Robert H. Fernald, Arthur M. Greene, Jr., Wm. B. Gregory, Ira N. Hollis, *President*, Charles T. Plunkett, new members; John H. Barr, R. M. Dixon, *Chairman Finance Committee*, James Hartness, D. S. Jacobus, W. B. Jackson, Spencer Miller, John A. Stevens, and Wm. H. Wiley, *Treasurer*, F. R. Hutton, Hon. Secretary, and Past-Presidents Jesse M. Smith and Worcester R. Warner; Henry Hess, I. E. Moultrop, Chairman of the Publication Committee, and Calvin W. Rice, *Secretary*.

Condensed Catalogues. The report of the referendum on Condensed Catalogues was received. This report indicated a vote to date of the meeting of 2373 for the continuance of this publication and of 334 against it. Thereupon the Council voted to continue the publication.

United Engineering Society. E. G. Spilsbury was elected a Trustee of the United Engineering Society.

Engineering Foundation. W. F. M. Goss was nominated to the Board of Engineering Foundation to represent this Society.

John Fritz Medal Board. John R. Freeman was elected a Trustee of the John Fritz Medal Board to represent this Society.

Executive Committee. President Ira N. Hollis, D. S. Jacobus, John H. Barr, Arthur M. Greene, Jr., C. T. Main and Spencer Miller were appointed as the Executive Committee of the Council for 1916-17.

Major Wm. H. Wiley, F. H. Clark, and C. C. Thomas were appointed Honorary Vice-Presidents to represent the Society at the Congress of Constructive Patriotism of the National Security League to be held in Washington, Jan. 25, 26 and 27.

Regular meetings of the Council are to be held on the third Friday of each month.

The following minute was passed by the Council and directed to be entered as a part of the record of the meeting of December 8:

Voted: That the Council here assembled record upon the minutes of the Society its sincere appreciation of the untiring, unselfish and earnest service rendered the Society during the past year by its President, Dr. D. S. Jacobus.

Calvin W. Rice,
Secretary.

PUBLIC HEARINGS BY THE BOILER CODE COMMITTEE

As announced in The Journal several months in advance, a Public Hearing on the Boiler Code was held on Friday and Saturday, December 8 and 9, 1916, in the Engineering Societies Building, New York, for the purpose of receiving suggestions relative to changes in the A.S.M.E. Boiler Code. This Hearing was in pursuance of the following recommendation of the Boiler Code Committee to the Council:

"Your Committee recommends that you appoint a permanent Committee to make revisions as may be found desirable in these Rules, and to modify them as the state of the art advances, and that such Committee should hold meetings at least once in two years at which all interested parties may be heard."

The Hearings began at 2 p.m. on Friday under the direction of Mr. John A. Stevens, Chairman of the Committee, assisted by fourteen members of the Committee. Discussion of the Boiler Code was entertained, beginning with the opening page of the Code and continuing through paragraph by paragraph to the Appendix. Everyone interested was given full opportunity to speak on each paragraph and all discussers were invited to submit their recommendations in writing after the Hearings. It was the purpose of the Committee to secure from those in attendance as much information as possible concerning the details of every rule in the Code, with a view to determining the desirability of making changes in them.

No replies or comments were given by the Committee mem-

bers on the Code requirements during the Hearings. The Committee has arranged to meet in January to consider the recommendations offered at the Hearings in greater detail.

The attendance at the Hearings was representative of all branches of the industry, including a large number of organizations interested in the steam boiler field, from the railroads, from the boiler manufacturers, from the makers of materials used in boiler construction, and from users of boilers. Some 1500 invitations had been sent out to all those on record as interested in steam-boiler construction, and a representative delegation was present. There was an unusual delegation from the various states and municipalities interested in the enforcement of steam-boiler regulations, which was largely due to the announcement made at the American Uniform Boiler Code Congress in Washington on December 4 and 5 (see reference to the Congress elsewhere in this issue), that every state and municipality that adopts the A.S.M.E. Boiler Code shall be entitled to have a representative present at all meetings of the Boiler Code Committee. Representatives were present from five states and from the Province of Ontario, Canada.

The very limited amount of discussion offered on the Code rules was a remarkable tribute to the comprehensiveness of the Committee's original work in 1914. Very little was offered in connection with the material specifications, the principal discussion being confined to the details of boiler construction and the fittings and appliances used therewith. The detail which entailed the longest discussion was the question of the extension of Par. 186 to permit of the welding of boiler joints by other than the forging process; the advocates of the several forms of autogenous welding presented an interesting array of data in this connection. But slight changes were suggested by the heating boiler interests and also relative to the rules for existing installations. Many helpful suggestions were offered by the representatives of the various states. All of these are at present under consideration by the Committee and will be given detailed study at the meeting in January.

Symposium and Annual Reunion

On Thursday of the Annual Meeting there was held a Symposium on Aviation. Charles M. Manly, Mem.Am.Soc. M.E., consulting engineer of the Curtiss Aeroplane & Motor Co., of Buffalo, N. Y., introduced the topic with an address on the early history of aviation, covering the development from the earliest efforts recorded to present-day practice. A particularly interesting part of his talk was that which dealt with the work of Professor Langley, of the Smithsonian Institution, with which the speaker had been associated, having been the designer of the motor and operator of the machine in its trial flights.

Mr. Manly followed his paper with the presentation of a number of lantern slides illustrative of the history of aviation, and finally a motion picture of the original Langley machine as it appeared in some recent flights when it was equipped with pontoons so that it could start from the water, and had installed a new motor and propeller, and was flown over Lake Keuka.

The second speaker was Glenn L. Martin, formerly of The Martin Co. and now vice-president of the consolidation of this company with the Wright Co., known as the Wright-Martin Co. Mr. Martin has been concerned with the building of aeroplanes for the Government, especially in California, and has a record of no serious accident with any machine of his type. His talk took the form of a description of the sensations which are experienced in an aeroplane, particularly the first time one goes up, and his account of the ride which he gave Dr. Brashear over the San Jacquin was greatly appreciated by the many friends of "Uncle John" who were in attendance.

The man who is believed to be the only past-president of The American Society of Mechanical Engineers who ever piloted an aeroplane was the next speaker—James Hartness, who gave a very interesting resumé of his experience at the aviation school in Garden City last summer. At the end of his talk Mr. Hartness was surprised perhaps as much as his audience by having a view of himself in an aeroplane flashed on the screen.

The last speaker was R. B. Lea, secretary of the Sperry Gyroscope Co., Brooklyn, N. Y., who showed first by a model of a gyroscope and later by lantern views and motion pictures how the principle of the gyroscope is utilized in keeping an aeroplane on an even keel, or stabilized. Motion pictures taken from the aeroplane when it was flown around the Statue of Liberty and below and above the East River bridges showed these familiar objects of the metropolis from new and unusual viewpoints.

Following the symposium those interested in dancing were invited to go to the fifth floor of the Engineering Societies Building, and others who preferred visiting with one another were accommodated on the eleventh floor of the Society's headquarters, where Dr. and Mrs. Hollis, with Mrs. Torrey and a number of the members of the Ladies Committee acted as host and hostesses, and supper was served.

Dr. and Mrs. Jacobus were host and hostess on the fifth floor. At about 11:30 p.m. a recess was taken and supper served on this floor and also on the sixth floor, after which dancing was resumed until about two o'clock.

Smoker at Annual Meeting

Following the precedent established a year ago, a smoker was held in connection with the Annual Meeting on Wednesday evening, December 6, 1916, this time on the fifth floor instead of in the Society's rooms on the eleventh floor. As members and guests entered they were handed a blue box with the Society's name and emblem in gold on the cover, containing cigars, cigarettes and matches, which not only saved the bother and confusion of passing each smoker his needs during the evening, but also provided those attending with a souvenir of the occasion.

Frank B. Gilbreth, Mem.Am.Soc.M.E., opened the entertainment program with a short talk on his experience on a trip to Europe during the war, and in his inimitable way of making even sober things funny, he described the search of the ship in which he crossed and numerous incidents connected with its convoyance to port. His talk was illustrated with lantern views which were especially interesting when it was known under what circumstances they were taken, as from portholes or behind barriers, for under the conditions the camera could not be used in the open.

Edwin J. Prindle, chairman of the Entertainment Committee of the New York Section, presided at the smoker, and following Mr. Gilbreth's talk told some good stories himself and then introduced the performers in the vaudeville program provided, including a ventriloquist, tenor soloist, two monologists, musical comedy specialist, magician and pianist.

Refreshments were served during and after the program. About seven hundred were in attendance.

College Reunions

As in previous years, Friday night of the Annual Meeting was "College Reunion Night," and reunions were held by the Engineering Alumni of the following institutions in New York and vicinity:

Brown University Alumni gave a banquet at Brown University Club.

Cornell University Alumni gave an informal dinner at the Cornell Club.

Lehigh University Alumni held an informal dinner and smoker at the Machinery Club.

Massachusetts Institute of Technology Alumni gave an informal dinner at their Club.

Pennsylvania State College Alumni held an informal "get-together" reunion dinner and smoker at Hotel Navarre.

Polytechnic Institute of Brooklyn Alumni held its reunion at the Engineering Societies Building, at which Frank Gilbreth delivered a lecture on Motion Study.

The Purdue Club of New York gave an informal dinner at the Phi Gamma Delta Club, in honor of Dean C. H. Benjamin of Purdue University, newly elected a Vice-President of the Am.Soc.M.E.

Stevens Institute of Technology Alumni gave their annual theater party, followed by a dinner at Hotel Astor.

University of Illinois Alumni gave an informal dinner at Stewart's Restaurant.

University of Michigan Alumni gave "a regular Michigan smoker" at Keen's Chop House.

Worcester Polytechnic Institute Alumni held an informal dinner in the ballroom of the Hotel McAlpin.

Annual Meeting Excursions

Eight well-attended excursions to points of engineering interest in New York and vicinity were held in connection with the Annual Meeting. The places visited were the Telephone Building, New York City; the Equitable Building, New York City; the Otis Elevator Company, Yonkers, N. Y.; the Essex Station of the Public Service Company of New Jersey; the Stevens Milk Company, Brooklyn; the Loose-Wiles Biscuit Company, Long Island City; the New York Steam Company; New York City, and the New York Navy Yard, Brooklyn.

Plans for the excursions were in the hands of a committee of eleven, of which John N. Norris was chairman, and members of the committee acted as personal guides to introduce participants, review the features of the trip and furnish the necessary information. The accounts of the excursions are perhaps best given in the words of the guides themselves:

EQUITABLE BUILDING

On the second day of the Annual Meeting a party of members and guests of the Society visited the Equitable Building, said to be the largest office building in the world, and were fortunate in having the features of its mechanical equipment explained by the Chief Engineer. This building occupies an entire block, and extends from 55 ft. below the street to 548 ft. above it. It has 40 numbered floors and 3 basements, each of an area of about 50,000 sq. ft. To serve the 15,000 tenants and those who transact business in the building there are 6 bays of 8 latest-type traction elevators. The elevator journey from the street to the fortieth floor takes a little over one minute.

In the lowest basement the building has its own power plant, supplying heat, water, fire protection and refrigeration. The spacious engine room contains three 600-kw., two 300-kw., and one 200-kw. 240-volt direct-current engine-type generators, each driven by a horizontal, side-crank simple steam engine working at about 150 lbs., and about atmospheric exhaust.

The boiler room contains two 550-hp. and five 450-hp. water-tube boilers, arranged for use with mechanical stokers. The fuel usually burned is a mixture of soft coal and No. 3 buckwheat which is stored in three bunkers, of 800, 200 and 1000 tons capacity, respectively. On account of the great height of the building natural draft is more than sufficient for combustion purposes.

The exhaust steam from the engines is used for heating the building and for making ice. Heating is on the vacuum system, and generally an ample supply of heat can be provided without raising the pressure above atmospheric. The exhaust steam passes to an oil separator to which is attached a 30-in. riser that goes straight up to the roof. Steam for heating is taken off at the thirty-sixth floor. There is a separate system of mains for the street floor, and some of the radiators on this floor only have thermostatic control. The absorption ice machines have a capacity of 12 tons of cake ice and 100 tons total refrigeration a day. Refrigerated brine is also furnished to the restaurants in the building. As some of the brine must be pumped to the top floor, the gauge shows pressures exceeding 350 lbs.

In the pump and compressor rooms there are ejector and sump pits, vacuum pumps, compressors for the ejectors, house pumps, fire pumps, a water-filtering plant, etc. The house pumps develop pressures of 280 lbs. and more. The fire pumps have on test developed a pressure of 50 lbs. at each of four 1-in. nozzles on the roof. A duplicate system of steam mains and water connections is provided for the pumps so that no emergency is likely to disable the whole plant. There is no central exhauster for vacuum cleaning, but each floor is equipped with portable motor-driven cleaners.

Selby Haar.

STEVENS MILK COMPANY

The excursion to the gas-power plant of the R. F. Stevens Milk Company, Brooklyn, New York, was of especial interest. This plant is a new installation and consists of producer-gas engines for operating refrigerating machines and for generating electric current for both power and lighting purposes. The plant consists of three 300-hp. suction-type anthracite producers using pea coal; three 250-hp. four-cylinder four-cycle vertical-type gas engines, and one three-cylinder four-cycle gas engine of 150-hp. Two of the four-cycle engines are belted to refrigerating machines and are used for cold storage and ice making. The third four-cylinder engine is direct-connected to a 150 kw. direct-current generator, and the 150-hp. three-cylinder engine is direct-connected to a 100 kw. generator, furnishing current at 250 volts for general power purposes round the plant.

J. H. Norris.

ESSEX STATION, P. S. CO. OF N. J.

The Essex Station is situated on the Passaic River, about two miles below and east of Newark, N. J. The location gives exceptional facilities for condensing water, coal supply and storage, ash disposal, etc., and furnishes a proper electrical distribution center.

The present buildings will house approximately one-half of what is considered the ultimate capacity, although since the plant is built on the unit principle it is capable of indefinite expansion.

The boilers are placed at right angles to the generator room, and a separate building houses the electric switches, feeders, bakery, etc.

The main generating units consist of two 25,000 kva. turbines with direct-connected exciters. These turbines are supported from the basement floor line on steel framing, leaving maximum room for access to condensing apparatus.

For each turbine there are installed four 1373 hp. water-tube boilers with superheaters and underfeed stokers. The furnace gases pass through economizers and induced draft fans to self-supporting steel brick-lined stacks 250 feet high above the grates.

Much care was taken in the equipping of the station to obtain apparatus that would facilitate economical operation and also

promote the safety and convenience of the operating force.

Many thanks are due to the company for their trouble in seeing that every one who participated in the excursion had an opportunity for a thorough examination of the station.

A. T. Nickerson.

NEW YORK STEAM COMPANY STATION "A"

The New York Steam Company has several central stations delivering high-pressure steam through pipes in the streets for both power and heating purposes in New York City. Station "B" serving the downtown district for the past 35 years has an installation of 58 boilers with a normal capacity of 16,000 hp., while the new station "A" has but 12 boilers with a capacity of 24,000 hp. This is in keeping with the progress in the matter of installation of steam mains, etc., of today as against the methods first used.

The station building is 107 ft. x 116 ft., and while in reality there are only four floors, the building is equivalent in height to ten stories. The tops of the stacks are 300 ft. from the ground. The ground floor is given up to the station auxiliaries—boiler-feed pumps, city-water service pumps, blowers, etc. All station auxiliaries will require about 1500 Boiler hp. when the station is operating at maximum capacity.

The first floor has six boilers in units of 1000 hp. normal rating each, but to be operated at 200 per cent capacity. They are automatically stoked and equipped with traveling grates for burning the smallest screenings of anthracite coal.

For steam purposes Croton water is used but is softened before entering the boilers. The service pump suctions are connected direct to the City mains with water meters between pumps and mains.

The second floor is laid out the same as the first making the total of 12 boilers. Above the second floor is the coal bunker of 3000 tons capacity. At the south end of the building are the storage bunkers—capacity 5000 tons coal storage and also the ash bunkers above referred to.

Sufficient scientific apparatus is installed to give complete detail for checking the efficiency of the individual boiler or the entire plant. The operation of the plant under maximum conditions will require thirty men, which is a saving of 75 per cent over the methods in the old station.

The steam is delivered from the plant to the street mains, whence it is distributed to the consumers both for power and heating purposes. Among the larger power consumers are several of the biggest office buildings, and it is not generally known that such large buildings as these have their own plants for the generation of electrical current for both power and light and secure their steam from the street service to drive their engines. This has been proved both practical and economical and high-speed engines have run for years without any bad effects.

Claude Hartford.

BROOKLYN NAVY YARD

The annual excursion to the Brooklyn Navy Yard was held on December 8 and was well attended as on previous occasions. The party was received by the officers assigned by Admiral Usher and Captain Burd, and through their courtesy the members were allowed to inspect practically every part of the principal navy yard in the country.

A sight of great interest was the part of the yard where the superdreadnought *New Mexico* is now being built. This enormous ship will have a displacement of 32,000 tons and will be one of the largest in the navy.

The battleship *Arkansas* being in the dry dock for overhauling was available for inspection and some of the members went over the ship from bow to stern.

Although the large ships attracted most of the attention, nevertheless the torpedo boats, destroyers and submarines were not neglected.

The trip through the large machine shops proved that the Navy Yard is not an assemblying plant, as here were visible huge machines for turning out engines, turbines, turrets and various other apparatus necessary for complete ships. The large Diesel engines which were placed on two of the Navy colliers during the last year were built complete in this yard and one of these ships was in the harbor on the day of the excursion.

The plate shop, power plant and boat-building shop were also visited. In the last mentioned shop an exhibition was given of the method which is now used for dropping the life boats into the water quickly. Tenders and life boats were also shown in the various stages of construction.

John H. Lawrence

LOOSE-WILES BISCUIT COMPANY

The varied uses to which machinery can be put in an establishment, such as is maintained by the Loose-Wiles Biscuit Company, will ever be of absorbing interest to mechanical engineers. The applications of machinery at the plant held the sustained interest of the party during the entire trip.

The company generously provided guides who, starting from the roof, conducted the party down floor by floor, to the basement, showing the methods of sifting and distributing the flour to the dough mixers, the batch wagons in which the various doughs or batters are allowed to raise; then the biscuit-cutting machines and the ovens for baking, and finally the assembling and packing departments.

Of especial interest was the machinery for baking and cutting the sweet sugar-lined wafers, and the methods of making the many fancy biscuits. At the conclusion, each of the party was presented with a box of fancy crackers.

The power plant was also visited. This consists of water-tube boilers, steam turbine and a-c. generators. The engine room was a particularly interesting place.

J. H. Norris.

THE TELEPHONE BUILDING

An excursion to the Walker Street Telephone Building of the American Telephone & Telegraph Company was made December 6. Messrs. G. W. Peck, H. G. Spohr and A. C. Vinal of the Telephone Company accompanying the party.

On arrival at the telephone building guides were assigned and the party was taken to the third floor where the incoming cables are received and separated on to the incoming cable racks. Here is also located a large rack upon which are mounted relays and other instruments, a large fuse board with indicating lamps, and indicating fuses. Closely adjacent are located the testing boards and testing apparatus, by means of which the cables are tested at frequent intervals. In one part of the room is a switchboard and motor generator sets used for charging storage batteries, and in an adjoining room a storage battery installation is arranged. On the third floor are also located the arrangements for handling various telegraph lines and connections, most of which are leases.

The guides explained thoroughly the entire scheme of installation, opening man-holes, uncovering switchboard connections, and in other ways showing plainly and clearly just how the vast number of various pairs of wires are handled. On the fourth floor the switchboards handling long-distance calls for the metropolitan district are located. The guides demonstrated the working of all the instruments and traced out the route of calls originating in this district for cities at a distance. The operation of the recording board, directory board, distributing table, and various connected departments on this floor were thoroughly explained and demonstrated. On this and the floor above are located all of the active switchboards with their allied departments handling incoming and outgoing long distance telephone calls for New York City and surrounding territory. The operation of the board handling incoming calls from a distance, as well as the operation of the department which continually checks the efficiency of the individual operators, was shown. It was shown that in handling a long-distance call between a point in New York City and a point in Pittsburgh from seven to nine different operators were involved, as well as many thousand dollars worth of equipment.

In this building is maintained a school for instruction of candidates for positions as switchboard operators, and this school being in session an excellent opportunity was afforded the party to follow every step of the course. Particularly impressive was the great care paid to ventilation, lighting and other particulars which have a bearing upon the health and efficiency of the operator. Another impressive feature was the number of supervisors employed: about one to every five operators. In general this excursion was exceedingly pleasant and interesting.

E. S. Cooley.

CANDIDATES FOR MEMBERSHIP

TO BE VOTED ON AFTER FEBRUARY 10, 1917

THE American Society of Mechanical Engineers is an organization for mutual service of over 7500 engineers and associates cooperating with engineers. The membership of the Society comprises Honorary Members, Members, Associates, Associate-Members and Juniors, all elected by ballot of the Council. Application for membership is made on a regular form furnished by the Secretary which provides for a statement of the standing and professional experience of the applicant and requires references from voting members personally acquainted with the applicant. The requirements for admission to the various grades will be furnished upon request.

Below is the list of candidates who have filed applications for membership since the date of the last issue of The Journal. These are classified according to the grades for which their ages qualify them, and not with regard to professional qualifications, i.e., the ages of those under the first heading place them under either Member, Associate or Associate-Member, those in the next class under Associate-Member or Junior, and those in the third under Junior grade only. Applications for change of grading are also posted.

The Membership Committee, and in turn the Council, urge the members to scrutinize this list with care and advise the Secretary promptly of any objections to the candidates posted. All correspondence in this regard is strictly confidential. Unless objection is made to any of the candidates by February 10, 1917, and providing satisfactory replies have been received from the required number of references, they will be balloted upon by the Council. Those elected will be notified about March 15, 1917.

NEW APPLICATIONS

FOR CONSIDERATION AS MEMBER, ASSOCIATE OR ASSOCIATE MEMBER

California

EDMONDSON, WILLIAM G., Mechanical Engineer, Interstate Commerce Commission, San Francisco

Connecticut

PECK, CARLOS C., Foreman Rolling Mill, Bridgeport

WEST, ERNEST H., Assistant Superintendent, Bridgeport Wks., Remington Typewriter Co., Bridgeport

Florida

BAKER, C. T., Chief Engineer, Southern Utilities Co., Jacksonville

Iowa

RANSOM, WILLARD G., Salesman and Engineer, The Bettendorf Co., Bettendorf

Massachusetts

ALLEN, CHARLES L., Treasurer and General Manager, Norton Co., Worcester

DOUGLAS, ROBERT C., New York State Representative, Norton Co., Worcester

DUNBAR, HOWARD W., Assistant Chief Engineer, Norton Grinding Co., Worcester

LOVEJOY, FRANK O., Assistant Manager, The Fiberloid Co., Indian Orchard

OWEN, OSCAR L., Patent Attorney, Whitin Machine Works, Whitinsville

SMITH, EDWARD F., President and General Manager, Greenfield Machine Co., Greenfield

Michigan

DRUMMOND, R. S., General Manager and Vice- President, Detroit Steel Products Co., Detroit

Minnesota

AUSTIN, CLEM C., Salesman, American Hoist & Derrick Co., St. Paul

COMSTOCK, ELTING H., Professor of Mine Plant and Mechanics, School of Mines, University of Minnesota, Minneapolis

Missouri

COX, CHARLES G., District Manager, McIntosh & Seymour Corp., St. Louis

New Jersey

RIEWERTS, MAX, Assistant Chief Engineer, Botany Worsted Mills, Passaic

New York

BARTLETT, PAUL, Mechanical Engineer, American Technical Advice Co., Woodhaven

BARRY, RALPH E., Marine Engineer, Tebo Basin, Brooklyn

LAWRENCE, WILLIS, Chief Mechanical Engineer, Lexington Building, Interboro Rapid Transit Co., New York

ROBINSON, JOHN R., Power Plant Specialties, New York

RUE, ERNEST F., Superintendent, Engineer, Steam Ship Dept., Vacuum Oil Co., New York

Pennsylvania

GEARHART, J. A., Secretary and Treasurer, Gulick-Henderson Co., Pittsburgh

NUSBAUM, LEE, Member of Firm, Pennsylvania Engineering Co., Philadelphia

SYKES, MATTHEW A., Superintendent, Remington Arms Co., Eddystone

WOOD, JAMES H., Field Engineer, Southwark Foundry & Machine Co., Philadelphia

Tennessee

MITCHELL, WILLIAM L., Department Chief, Tennessee Department of Workshop and Factory Inspection, Nashville

Vermont

BEARDSLEY, WILLIAM H., Assistant Superintendent, Jones & Lamson Machine Co., Springfield

Canada

COOLIDGE, C. E., Formerly Chief Engineer, Howitzer Dept., The Canadian Fairbanks-Morse Co., Toronto

HARRIS, CHESTER G., Assistant to Manager, Dufferin Plant, Russell Motor Car Co., Toronto

TISSINGTON, FRANK, Chief Draftsman, McKinnon, Holmes & Co., Ltd., Sherbrooke

Philippine Islands

DUFFY, OWEN, Superintendent and Chief Engineer Insular Cold Storage and Ice Plant, Manila

Russia

SATKEVICH, ALEXANDER, Professor of Mechanical Engineering, Nicolas Academy of Engineers, Petrograd

FOR CONSIDERATION AS ASSOCIATE-MEMBER OR JUNIOR

District of Columbia

BURDICK, HAROLD S., Lieutenant (j. g.), United States Navy, Washington

Illinois

STARK, JULIAN E., Chief Draftsman, Crane Co., Chicago

YOUNG, WILLIAM V., Vice-President, The American Appraisal Co., Chicago

New Jersey

VOIGT, MAX T., Tool Draftsman, Bosh-Magneto Co., Plainfield

New York

BROWN, CLINTON B., Erecting Engineer, Henry Worthington, New York

NECROLOGY

HARRY D. JOHNSON, JR

Harry Dibrow Johnson, Jr., was born in South Bend, Ind., on July 29, 1882, died in that city Noveber 11, 1916.

Mr. Johnson received his early education in the public schools of South Bend, after which he entered Cornell University, graduating in 1904. Immediately he was employed with the General Electric Company at Schenectady, N. Y., and after two years returned to South Bend for responsible work with Studebaker Brothers Manufacturing Company. During the first seven years he progressed from machinist and draftsman and assistant master mechanic, having charge of building, design and construction, power-plant operation, machine design, maintenance, repairs, methods, piece prices, factory layouts, design and construction, to the position of master mechanic and extension work director.

Mr. Johnson's varied interests included public enterprises and general charities, as well as memberships in the University Club of Chicago, the Indiana Club, the South Bend Country Club, and the Chamber of Commerce. In 1912 he became a Junior Member of the Society.

CLIFFORD E. LIPE

Clifford E. Lipe was born December 23, 1887. Securing his earlier education in the public schools of Syracuse, N. Y., he entered Cornell University and graduated from the school of engineering of that university in 1911. On a year's trip abroad he studied the automobile business from an engineering and manufacturing standpoint, and on return was engaged immediately to look after the engineering work of the Brown-Lipe Gear Company. He became chief engineer of that company, having charge of experimental engineering, including developing and testing new transmission devices, testing accessory devices brought to that company by designers and inventors, and designing or developing the company's line of four-speed transmissions. As engineer and designer with the C. E. Lipe Manufacturing Company, he designed a great variety of special devices, tools, jigs and fixtures, including a special automatic machine for drilling and reaming solid steel ball retainers. He became vice-president of the Brown-Lipe Gear Company, being a member of the Board of Directors and very instrumental in dictating the business policy of that company.

He was elected to Associate Membership in the Society in 1914.

ALFRED WATERS PROCTOR

Alfred Waters Proctor was born in Needham, Mass., May 26, 1878. Having from early youth an inclination toward things mechanical, he determined to fit himself for mechanical engineering, and in 1899 entered the Massachusetts Institute of Technology.

On leaving the Institute, Mr. Proctor acquired his first experience by working as designer and draftsman in the plants of Blanchard Machine Company and Burton Electric Smelting Company, and with Carl L. Sponholtz, architect, all in Boston. He was later employed as designer of machine tools with Western Electric Company, and in the manufacture of pyrographic tools with J. G. Tyssowski Company, Chicago, Ill.

Much of his time was devoted to inventions and the design of special machinery, for the manufacture of which he operated shops of his own in Washington, D. C.

From 1907 to 1915 he maintained an office in New York City, during which time he made a number of special investigations, including tests on inventions of pumps, tests with pumping and engine apparatus and tanks to determine the highest efficiency of differently-shaped siphon bowls, tests on speed of type bars for the Royal Typewriter Company, reports on inventions for the Crown Cork and Steel Company, chronograph tests on shoe machines for Reece Button Hole Machine Company, and ball-bearing measurements for the Hess-Bright Manufacturing Company.

Mr. Proctor was for seven years an examiner in the United States Patent Office, and during that time attended and graduated from Columbia University Law School, and was admitted to practice as a lawyer by the Court of Appeals of the District of Columbia and by the Supreme Court of the United States. Because of his peculiar qualifications, which now included a thorough training in the theory and practice of engineering and a wide knowledge of patents and patent laws, his services were sought as an expert in patent litigation. His success in this capacity resulted in his being retained in some of the most important patent cases before the courts in recent years, and his standing with the members of the patent bar, and the confidence and respect with which the judiciary regarded his work were such that in several cases he was invited to sit with the court as a technical adviser. It had been with some reluctance, however, that he relinquished his active work as engineer, having always a preference for actual constructive work, and he continued to act frequently as a consulting engineer.

Mr. Proctor was elected to membership in the Society in 1916, and was also a member of the University Club, the Knickerbocker Field Club, and the Young Men's Republican Club, all of Brooklyn, and of the Technology Club of New York City. His death occurred on September 10, 1916.

HUBERT LEIGH WATSON

Hubert Leigh Watson, who died in New London, Conn., October 11, 1916, was born in Philadelphia, Pa., September, 1888. He was educated in the public schools of Hackensack, N. J., and later entered Cornell University for a course in mechanical engineering, taking his degree in 1910. The following year he pursued advanced work in gas-engine design.

For practical experience, Mr. Watson began with the summer of 1909 to employ his vacation time in apprenticeships, at that time as machinist's helper in the repair shops of the Delaware, Lackawanna & Western Railroad at Kingsland, N. J.; in 1910 he worked with the American Car and Foundry Company at Berwick, Pa., in its steel car department, and in 1912 and 1913 was employed with the De La Vergne Machine Company, New York City, in erecting and testing oil engines, also doing some special tool designing.

From 1911 to 1915 he was instructor in practical mechanics in Purdue University. He was in charge of the course in gas-power-plant design and taught all sections in mechanism.

In July, 1915, he resigned from Purdue University to accept a position with the New London Ship and Engine Company, of Groton, Conn.

He published an article on Accelerating Force of Reciprocating Parts in *Machinery,* August 1916.

Mr. Watson was a member of Purdue Cosmopolitan Club, and in 1913 became a Junior Member of the Society.

AMONG THE SECTIONS

On Tuesday, Wednesday and Thursday of Annual Meeting Week, the official delegates of sixteen of the twenty Sections of the Am.Soc.M.E., and representatives of five centers contemplating the establishment of Sections, met in conference with the Committee on Sections.

A great deal of valuable information as to the special conditions obtaining in various localities was developed and useful suggestions made which should do much to enhance the interest in this most important phase of the Society's activities.

On the first day of the Conference the delegates met at luncheon with the members of the Council and officers-elect. On that occasion the President and President-Elect took advantage of the opportunity to voice their keen interest in the activities of the Sections, and their desire for correlation of their work with that of local engineering interests whenever possible. That the Society is taking a leading part in this spirit of coöperation was evidenced by the fact that there were present by invitation at the first day's session of the Conference, representatives of the other three Founder Societies in the persons of T. J. McMinn, Assistant Secretary of the A.S.C.E., W. H. Hall, Chairman of the Sections Committee of the A.I.E.E., and A. D. Beers of the A.I.M.E.

The Sections represented and their official delegates were:

Atlanta	Earl F. Scott
Birmingham	Paul Wright
Boston	A. L. Williston and W. G. Starkweather
Buffalo	C. H. Bierbaum
Chicago	Joseph Harrington
Cincinnati	A. J. Baker
Detroit	M. E. Cooley
Indianapolis	William H. Insley
Milwaukee	Edward Hutchens
Minnesota	J. V. Martenis
New Haven	J. W. Roe
New Orleans	William B. Gregory
New York	H. R. Cobleigh and John H. Norris
Philadelphia	D. Robert Yarnall
St. Louis	Hans R. Setz
Worcester	Edgar H. Reed

There were also present representatives from the following localities:

Hartford	J. Breslav
Lowell	A. W. Vaughan
Meriden	C. H. Decherd
Providence	W. H. Paine and A. H. Annan
Rochester	Lucien Buck

SCOPE OF THE CONFERENCE

The first day of the Conference was given over to an "Experience Meeting," at which each delegate reported the work of his Section during the past year and plans for the ensuing season. A report was made by the Committee on Sections giving a resumé of what it has accomplished in the second year of its work. This report is appended.

The first section brought out the facts that generally all Sections are closely coöperating with existing engineering societies and clubs in their respective localities and thereby securing greater interest on the part of all engineers, the presentation of a higher class of papers, a better spirit of "get-together" and good fellowship and the establishment of a permanent headquarters for the engineers of the locality. Ways and means for the continuance of this forward movement were discussed, and among others the following were advanced:

1. The desirability for "pre-meeting" suppers at a reasonable price which would encourage general participation and afford opportunity for increasing acquaintanceship.
2. Provision for all attending each meeting to wear a badge, giving their names to assist in acquaintanceship.
3. The desirability of all coöperating to the utmost in this matter of good fellowship and "get-together" movement, and especially on the part of the older members in relation to the newcomers.
4. The wisdom of having short papers, well presented and not too technical in nature, with prearranged intelligent and snappy discussion and adjournment in season to enable the members to mingle for a social hour and partake of a lunch,—"Dutch" or otherwise.
5. Excursions to points of engineering interest and industrial plants, which afford opportunity for getting acquainted while learning something of value.

The subsequent sessions were taken up by a thorough discussion of proposed changes in the By-Laws of the Society with regard to rules covering the administration of the Sections, and when these are finally decided upon they will be published in The Journal.

PUBLICITY

The Conference considered that particular attention should be paid to Sections' publicity. Advance notices of meetings should not only be sent for publication in The Journal, but also to newspapers and technical papers; reporters should be invited, and abstracts of papers furnished them if desired. Publicity for the engineer has long been overlooked, and this is largely responsible for the lack of appreciation on the part of the community of the prominent part taken by engineers in public relations.

Proper methods will do much to broaden the interest of engineers and afford them equal recognition with the legal and medical fraternities, which on account of the human element in their professional work are today exerting such a strong influence in the activities of the community.

Report of the Second Year's Work of the Committee on Sections, 1916

The first year of the activities of the Committee on Sections was devoted largely to formulating a policy which would provide for a uniform administration of the Sections with regard to their relations with the parent Society and without conflicting with conditions peculiar to their respective localities. This was accomplished through the medium of two conferences of Sections' delegates (one at each of the two general meetings held in 1915) supplemented by a large volume of correspondence.

During the past year it has been possible to inaugurate a number of innovations in the Sections' activities and it is believed that the coöperation afforded by the Society has been rewarded not alone by increased interest on the part of members located in the territory covered by the several Sections, but also through stimulating members in several districts to undertake the establishment of new Sections.

At the time of the last Section Conference in December 1915, there were Sections at the following centers: Atlanta, Birmingham, Boston, Buffalo, Chicago, Cincinnati, Los Angeles, Milwaukee,

Minnesota, New Haven, New York, Philadelphia, St. Louis, San Francisco and Worcester. The Birmingham Section was authorized at the meeting of the Council held in December 1915. Since then five Sections have been added to the list: Baltimore, Detroit, Erie, Indianapolis, and New Orleans. Two of them, Baltimore and Erie, have been authorized in December, 1916, so that we now have twenty Sections of the Society.

There are a number of industrial centers where conditions appear to be ripe, or nearly so, for the organization of Sections, or where meetings may be held in conjunction with Sections already existing. Among these places may be mentioned Cleveland, Columbus, Hartford, Kansas City, Lowell, Meriden, Providence, Pittsburgh, Rochester and Toledo. It is suggested that existing Sections coöperate in spreading information as to the value of Sections in promoting the engineering profession and incidently the "Mutual Service" afforded by The American Society of Mechanical Engineers, because it is well that all who enter the Society do so with the understanding that they are getting an opportunity to *give* as well as *receive* service. One way in which Sections could coöperate in the development of new Sections would be to prepare an article giving concisely the value of the Section as they see it. This might be undertaken by a member of the Executive Committee who has had sufficient experience in the work to have a knowledge of what may be termed a composite opinion of the members of the Section with regard to its worth to them. A series of such articles could be used to considerable advantage by the Committee on Sections in formulating a pamphlet for distribution in localities where Sections are proposed.

During the year the President, Secretary, or Chairman of the Committee on Sections has visited practically all of the Sections of the Society excepting those located on the Pacific Coast and they were visited in the fall of 1915. In addition visits were made to Baltimore, Detroit, Erie and Indianapolis on the occasion of the Organization Meetings held at those places.

CONSTRUCTIVE ACTIVITIES

Among others, the following developments have been achieved:

A proposed set of Amendments to the By-Laws of the Society, to govern uniformly the work of the Sections. These were submitted to the Sections' Conference at the Annual Meeting, December, 1916.

Unusual recognition was accorded the Sections by President Jacobus in giving each of five groups of Sections the privilege of electing one member of the Nominating Committee charged with the duty of selecting candidates for the Council on the ballot just closed.

Another illustration of the recognition of the importance of Sections is a Resolution by the Council to present at the 1917 Spring Meeting an amendment to the Constitution to make a Standing Committee of the Committee on Sections.

A "clearing house" for motion picture films on industrial subjects and lectures has been established, and a start has been made to secure written lectures, sometimes with slides, which lectures may be presented by a member of the Section who is willing to become sufficiently familiar with the subject matter to present it.

Sections have been assisted in their desire to encourage the young engineers just out of college through an additional amount added to their appropriations for each graduate Student Member who locates within their territory. In return the Sections are expected to give these graduate Student Members all the privileges of the Section for a period of two years after graduation. Thereafter it is expected that regular application will be made for membership in the Society if one expects to continue to obtain such privileges.

The various Sections have begun in a small way to coöperate with one another through an exchange of literature and notices of meetings. This should be further developed so that whenever a member of one Section expects to visit a city where another Section is established, notification be sent in advance and if possible arrangements be made whereby the Section visited may have opportunity to entertain the visitor and have him make some remarks, or if possible deliver a technical paper.

The Journal now devotes considerable space to a portrayal of the work of Sections, and it is hoped that the Sections will coöperate not only by submitting promptly reports of their activities, but also by keeping the Editor informed regarding all engineering news of their respective districts and especially proposed engineering developments. Every Section is encouraged to nominate one of its younger members to act as a correspondent of The Journal.

Transactions of the Society should be available for the members of Sections, and as fast as Sections secure headquarters where such Transactions may be properly cared for, it is planned to provide them.

UNIFORM DATE FOR CHANGE OF OFFICERS

Another accomplishment of the year has been to secure the consent of all Sections to uniformly elect their officers between March first and the end of May so that such elections may be formally reported and ratified by the Committee on Sections and the Council at their June meetings (held the second Friday of June) and the new officers thereby enabled to uniformly begin their activities on July first.

It is hoped by this procedure it will be possible for the Executive Committees of Sections to map out their programs for the ensuing year and have dates, speakers and places of meeting decided upon, and reports thereof sent to the Society's headquarters by October first of each year.

The most recent and one of the most successful achievements in Sections' activities was a Joint Meeting by the Boston, New Haven, New York and Worcester Sections and the Providence Engineering Society at New London, Conn., on November 11, 1916. Over sixteen hundred persons attended and special trains were run from Boston and Providence and New York and New Haven. In addition to being the first Joint Meeting of Sections ever held it was at the same time the largest gathering ever held under the auspices of the Society.

ELLIOTT H. WHITLOCK, *Chairman.*
W. F. M. GOSS,
L. C. MARBURG,
WALTER RAUTENSTRAUCH,
D. ROBERT YARNALL,
Local Sections Committee.

SECTION MEETINGS

BIRMINGHAM, OCTOBER 25

An enthusiastic meeting of the Birmingham Section was held October 25 at which W. P. Caine, Assoc.Am.Soc.M.E., gave a most interesting talk on The Use of By-Product Coke-Oven Gas as a Fuel and Some of the Problems Presented in its Use at the Ensley Steel Works.

The Tennessee Coal and Iron and Rail Road Company at its Steel Plant at Ensley has between 28 and 33 million cu. ft. of by-product gas to dispose of each day. This is the surpius made at their By-Product Coke Oven Plant at Fairfield and forced through a 24-in. pipe line 8000 ft. long ,and from the Semet-Solvay Ovens located next to the Ensley Plant.

In the talk the causes of the irregularities in the delivery and demand for the gas and the lack of a gas holder were brought out in order to indicate the conditions under which it has to be used and the necessity of being able to supplement or substitute some other fuel upon short notice sufficient to care for the variations.

Descriptions were given of various types of burners used, and their application to special conditions as for heating ladles, drying ovens, mixers, open-hearth furnaces, heating furnaces, soaking pits, etc.

All burners have a chamber in which the gas and air or a part of the air necessary for combustion are mixed before the mixture is ignited in the furnace. In some the air is drawn in by the gas jet or jets, while in others it is a jet of compressed air, air from a fan blower or air blown in with a steam jet.

Experience has shown that the burners will back-fire and burn in the mixing pipe with those in which the air is drawn in and if allowed to burn in this manner, the capacity is noticeably reduced and in some instances the end of the mixing chamber has burned off. This occurs when the gas pressure is lowered or its velocity is reduced by trying to draw in too much air for the proportions of the burner. To avoid this trouble a burner was made on the multiple-jet principle with a very short mixing chamber.

Following this talk, Mr. Gaboury, of the Woodward Iron Co., gave his experience on installations similar to those described by Mr. Caine. This was followed by H. P. Ryding, who called attention to the economies now effected as compared with what might

have been done had the entire installation been built new with a view to using by-product gas.

The chairman outlined the program for the coming season as follows: *December*, Flying Machines by Prof. M. T. Fullan, of Alabama Polytechnic Institute; *January*, Combustion and Combustion Chambers in Locomotive Practice, by A. T. Anthony; *February*, Dr. Ira N. Hollis, President, and Calvin W. Rice, Secretary of the Society; *March*, Illumination, by Prof. A. A. Wittig, of the University of Alabama; *April*, Prof. A. St. C. Dunstan, of Alabama Polytechnic Institute; *May*, annual meeting, Dr. Thornwell Haynes, President of Birmingham College.

Paul Wright,
Section Secretay.

BIRMINGHAM, NOVEMBER 15

The meeting held by the Birmingham Section on November 15 was its first anniversary meeting, and it was the general sense of the meeting that the Section had been successfully organized on a basis to do effective work. Two talks were given, illustrated by photographs and charts thrown on the screen by the new balopticon machine. The use of this machine is more or less original with this Section, and the results were highly satisfactory in every respect.

The first talk was given by Mr. Paul Wright, who showed a number of photgraphs illustrating the manufacture of cast-iron water-pipe. These pictures showed the operation from beginning to end of the American Cast Iron Pipe Company's plant at Acipco, Birmingham. This company manufactures 400 tons of pipe per day, and is the only pipe shop in the country that runs double shift; it also has the distinction of making pipe 16-ft. long, and is the pioneer in the manufacture of this long pipe.

Mr. J. H. Klinck led an interesting discussion of the paper by Samuel Insull presented at a meeting of the New Haven Section on April 5, 1916, The Progress of Economic Power Generation and Distribution. Each picture and chart was well illustrated by the balopticon. Mr. Klinck added several illustrations of his own experiences with different types of turbines.

In the discussion, Frank Cutler called attention to the fact that the consideration of a central power station for the Birmingham district might be the means of conserving considerable power, and at the same time take advantage of the diversity principle as strongly emphasized by Mr. Insull.

Paul Wright,
Section Secretary.

BUFFALO, NOVEMBER 1

At the meeting of the Buffalo Section held on November 1, Frank B. Gilbreth, Mem.Am.Soc.M.E., spoke on Motion Study; his lecture was illustrated with slides showing his well-known cyclograph, in which a light is fastened to the object whose motion is to be recorded, and the camera is opened to record the path of the lighted object. Mr. Gilbreth's lecture opened up many fields of thought and showed what could be done in further advancing the study of the elimination of waste, whether in motion or materials.

John Younger,
Section Chairman.

BUFFALO, NOVEMBER 15

Professor Wm. L. Cathcart, Mem.Am.Soc.M.E., addressed a meeting of the Buffalo Section on November 15 on The Navy; its Fleet and Naval Stations. His talk was illustrated with slides showing various phases of work in the Navy, including some splendid pictures of battleships. The speaker showed how the engineer was responsible for the modern fighting machine and pointed out that an engineer would be required more and more to express his feelings as regards the growth of a navy suitable for the adequate defense of the United States.

John Younger,
Section Chairman.

BUFFALO, NOVEMBER 29

Before the meeting of the Buffalo Section held on November 29, C. H. Bierbaum, Mem.Am.Soc.M.E. and Chairman of the Sub-Committee on Bearing Metals of the Research Committee, read a paper on Graphite, with special reference to its use in lubricating compounds for bearings. The paper described at the outset the experience of the Lumen Bearing Company in producing the most economic and useful bearings for particular purposes. The first field of investigation was that of the metallurgical treatment of bearing metals in the foundry; in addition it was found necessary to investigate and correct improper designs from the point of view of both the strength and proportion of the bearing, as well as the oil grooves. This in turn brought in the oil supply in general and lead to a broad investigation of the entire field of lubricants, and from the beginning of this investigation graphite promised to be a vital subject. The results obtained with this metal were so varied, however, and at times so unsatisfactory that they lead to special studies of the composition and impurities of graphite, finally resulting in the perfection of a process by means of which all objectionable impurities are removed; impurities such as mica, silicon, feldspar, iron oxide, alumina and clay to the amount of 30.7 per cent., have been removed by this process from some of the best lubricants on the market.

L. J. Foley,
Director of Publicity.

BUFFALO, DECEMBER 13

On December 13, Alfred P. Brush, consulting engineer, of Detroit, spoke to the Engineering Society of Buffalo on the Four-Cylinder Automobile Engine, and other engineering topics. Mr. Brush said in part:

"Considered solely from the standpoint of numbers, the four-cylinder engine is, and has been for the last ten years, the standard prime mover for self-propelled road vehicles, and in my judgment will continue to be, so long as the four-cylinder internal-combustion engine holds its place as the most satisfactory prime mover for mobile use.

It is my opinion that the six-, the eight-, and the twelve-cylinder motors have all been developed more nearly to their ultimate possibilities than has the four-cylinder engine, and it is also my opinion that the greatest obstruction to the development of the four-cylinder motor toward its ultimate possibilities has been and is its very popularity. Volume of production makes for efficiency of production and stagnation of development.

There is another very real obstruction to the development of the four-cylinder engine. It has come to be accepted as the engine for the extremely low-priced automobile.

Four of the leading manufacturers of four-cylinder-engined cars claim for their engines maximum horsepower per cubic inch of piston displacement ranging from 0.142 to 0.206, with total piston displacements ranging from 170 cu. in. to 213 cu. in., and maximum total horsepowers ranging from 25 to 35."

Mr. Brush then described a four-cylinder motor which has been produced during the past year and which developed over 0.2 hp. per cu. in. from 400 r.p.m. to 2600 r.p.m.

A general discussion of engines followed Mr. Brush's talk, and Chas. M. Manley of Curtiss Aeroplane Co., Russell Huff, Chief Engineer of the Dodge Company, David Fergusson, Chief Engineer of the Pleasure Car Department of the Pierce-Arrow Corporation, and others took part.

A local Section of the Society of Automobile Engineers was formed at this meeting. David Fergusson was elected chairman. The vice-chairman and secretary are Chas. M. Manley and David W. Sowers.

L. J. Foley,
Section Correspondent.

CHICAGO, NOVEMBER 17

The first meeting of the Chicago Section this season was held on November 17, and was announced as Army and Navy night. The chairman introduced William A. Moffet, Commander of the Great Lakes Naval Training Station, who told how naval cadets were prepared and showed numerous lantern slides of their quarters and features of their training. Beginning with the *Constitution*, the development of the navy was traced up to the last battleships off the ways.

It was the speaker's opinion that if we ever attain naval supremacy we must build ships larger, faster and with greater gun power than ever before; in other words, go the limit in the three features by which a battleship is rated. In this way the

present day dreadnaught or superdreadnaught would be outclassed and soon become obsolete. Physical limits would be reached in a battleship having a displacement of 60,000 tons, 18 in. guns and a speed of 35 knots.

Lucien B. Moody, Major, Ordnance Department, Rock Island Arsenal, spoke on the army ordnance department, showing views of its factories and products and the guns now used by the army. In time of war the five arsenals would supply only a small part of the munitions needed; it would be necessary to depend largely on the output of private enterprises.

Captain Christie, of the new United States Aviation Station at Chicago, outlined the methods of training aviators, the present status of the service and the hopes for the future. A review of the difficulties of the United States aviation corps in Mexico and anecdotes from the personal experience of the speaker were heard with great interest.

Robt. B. Thayer,
Section Secretary.

LOS ANGELES, NOVEMBER 2

A technical session of the Los Angeles Section met on November 2, when E. F. Soderholm, Mem.Am.Soc.M.E., delivered an address on Deep-Mine Hoisting, a subject which his experience qualified him to handle well. A dinner was served and attention was called to the meeting of the Engineers of Los Angeles every Thursday, at which there would be always something of interest to the members of this Section, and an invitation was extended them to attend these meetings.

Ford W. Harris,
Section Secretary.

MILWAUKEE, NOVEMBER 17

At a joint meeting of the Milwaukee Section with the Milwaukee Engineers Society and Milwaukee Section of the American Chemical Society on November 17, Prof. Otto L. Kowalke gave an address on the Characteristics of Base Metal Thermocouples. The address first described an investigation regarding the performance and constancy of base metal couples. For this purpose samples of couples had been purchased in the open market, the couples being calibrated against a carefully standardized platinum couple. First the couples were all calibrated with 4 in. of their lengths immersed in the furnace; second, calibration was made with 15 in. of their lengths immersed. Then the couples were all treated for 20 hours, respectively, at 400 deg. Cent., 600 deg. Cent. and 800 deg. Cent., and after each treatment the couples were separately calibrated.

The results of these treatments and calibrations showed that in many cases there were variations of 150 deg. Cent. between the calibration at 4 in. and 15 in. immersion. This difference was due to a lack of proper annealing before being put into service. Many of the couples gave very satisfactory performance and showed a variation in calibration of from 25 to 40 deg. from the beginning to the end of the test. This is not an excessive variation. Microphotographs of the wires were also made before and after heat treatment for two hours, respectively, at 400 deg. Cent., 600 deg. Cent., 800 deg. Cent. and 1000 deg. Cent.

In all cases where satisfactory calibration was found, it also happened that the metals composing the wires in the couple formed a solid solution. It was found that in each couple where silicon was used to an extent of about 3 per cent. a segregation of the metal took place, which resulted in an excessive change in calibration; the extent of this change being 150 deg. at 1000 deg. Cobalt was also investigated as a chemical element.

Various couples were made up with iron, *Advance*, nichrome and constantan wires. These couples were treated in a manner similar to those described above. It was found that cobalt *vs.* *Advance* or constantan gave satisfactory calibrations. Cobalt does not get brittle so easily as does nickel, nor does it oxidize quite so readily. A combination of cobalt *vs.* nickel-iron alloy gives a most satisfactory performance. There was less than 5 deg. difference between the original and final calibrations.

Fred. H. Dorner,
Section Secretary.

MINNESOTA, NOVEMBER 9

The Minnesota Section held its third meeting of the season in Minneapolis, Minn., on November 9. The speaker was Dr. E. F. Friedman, chief chemist of the McLaughlin, Gormley, King Co., of Minneapolis, Minn., who addressed the meeting on Coke and Its By-Products. The talk proved exceedingly interesting and was followed by a lively discussion, during which the opinion was expressed that the inferiority of the dyes manufactured in this country is due not to lack of knowledge, but to the fact that our manufacturers will not take the time to carry the reduction of the crudes down to the proper base.

D. M. Forfar,
Section Secretary.

NEW HAVEN, NOVEMBER 15

The Fall meeting of the New Haven Section, held on November 15, was held in two sessions as usual. At the afternoon session, papers were read on Methods of Testing Metals, by Prof. W. K. Shepard, and on Applied Metallography by Prof. C. H. Mathewson. These were followed by discussion of the subjects by Mr. Skinner, of the Westinghouse Company, Mr. Staples, Prof. L. P. Breckenridge, Mem.Am.Soc.M.E., and others. The Hammond Laboratory was thrown open to the meeting, and dinner was later served in the Yale Dining Club Hall to visiting engineers.

The evening session was opened by Calvin W. Rice, Secretary of the Society, who gave notice of the 37th Annual Meeting to be held in New York, December 5 to 8. Prof. Breckenridge announced that an exhibition would be given by the Yale Mechanical Engineers Club in the Mason Laboratory, December 8. A paper was read by S. J. Berard, Instructor in Machine Design of Sheffield Scientific School, on Methods of Duplicating Drawings, and Frank B. Gilbreth, Mem.Am.Soc.M.E., spoke on Developments in Time-Study Methods and Devices, both of which brought out considerable discussion on the application of photography to engineering. Mr. Berard gave an illustration of blueprinting by exposing a tracing in the stereopticon and almost immediately showing the blueprint on the screen. Programs were prepared by the blueprint department of the Mason Laboratory as examples of methods of duplicating from negatives.

A full account of this meeting is published elsewhere in this issue.

E. H. Lockwood,
Section Secretary.

NEW ORLEANS, OCTOBER 2

A joint meeting of the Louisiana Society of the members of The American Society of Civil Engineers and the New Orleans Section of our Society was held on October 2. The chairman announced a new policy for the Section, by which full coöperation might be maintained with the Louisiana Engineering Society without any conflicts of work. Under this policy, the preparation of new papers of merit is to be confined largely to the Louisiana Society, and the activities of our Section are to be devoted to the discussion of papers which shall have appeared either in The Journal or Transactions.

The topic of discussion of this meeting was the paper of G. C. Noble, entitled The Design and Test of a Large Reclamation Pumping Plant, published in the May, 1916, issue of The Journal and later selected by the Committee on Meetings for presentation at the Annual Meeting in December, 1916.

Professor Gregory and Messrs. Shaw, Hutson, Okey, Delery, Nelson, Dusenbury, Burwell and Olson participated in the discussion of this paper, bringing out a number of points of interest not previously developed. This discussion will be referred to Mr. Noble for his reply.

H. L. Hutson,
Section Secretary.

PHILADELPHIA, NOVEMBER 28

On November 28, a meeting of the Philadelphia Section was held in the auditorium of the Philadelphia Engineers' Club. Mr. MacCoull of the Westinghouse Machine Co., of Pittsburgh, spoke upon the subject of mechanical development of aviation. He pointed out that from ancient times, it has been man's insatiable ambition to conquer the air, and history from the earliest times is marked by accidents occurring from experiments with various types of flying machines. The most rapid progress in the development of air machines has occurred in the past ten years.

Mr. MacCoull's paper laid particular stress upon the development of aeroplane engines, and gave instances of engines developed to meet the requirements of the very least possible weight per h.p. It is almost unbelievable that successful engines have been constructed which weigh only three or four pounds per h.p. His lecture was illustrated throughout with a number of fine lantern slides showing the development of the aeroplane engine within the past ten years. Valve arrangements and cooling systems were also treated in his paper.

Following Mr. MacCoull's paper, Dr. C. E. Lucke, Mem.Am.Soc.M.E., Dean of the Department of Mechanical Engineering of Columbia University, gave a very graphic description of the problem of aeronautical engine design. Dr. Lucke is Chairman of the Advisory Aeronautical Committee, appointed by the War Department, and showed by his talk that he was intimately familiar with the difficulties involved in successful aeroplane engines. Dr. Lucke was somewhat pessimistic in his view of the situation as to the dependability of modern aeroplane engines. Take any five engines, Dr. Lucke said, and start them and leave them alone, and hardly three can be depended upon to run without attention for over two hours. He felt as if the problem was just beginning to be solved, and as soon as capital became interested in the matter and the manufacture of aero-craft took its place on a plane with other lines of industrial work, then would the development of the engine begin in earnest. It was estimated that it would require from $50,000 to $500,000 to develop a good aeroplane engine and embody all the most recent improvements.

Dr. Lucke talked about carburation, the necessity of lightest possible power plant, fixed cylinders versus rotary cylinders, ignition, engine housing, crank cases; analyzing his talk throughout with the use of curves drawn upon the blackboard. Dr. Lucke thought that not sufficient attention had been paid by designers to stresses involved, and emphasized the necessity for designing to meet the heat carrying conditions. The great problem, therefore, is to get together a sufficient amount of design data to enable engineers to handle the problem in a more scientific and thorough manner.

Although an American was the inventor of the present aeroplane, it is much to our shame that the last two or three years has seen Continental Europe considerably outdistance us in the progress made in aviation.

Discussion on the subject was led by Dr. Jos. A. Steinmetz of the Aero Club.

W. R. Jones,
Section Secretary.

PROVIDENCE, NOVEMBER 22

At the November meeting of the Providence Engineering Society, held in the Engineering Building of Brown University on the 22nd, definite steps were taken for the winter's activities by the formation of four sections, which with the section on fire protection previously organized make five sections to start with. The new sections are: Machine Shop, Efficiency and Scientific Management, Structural Engineering and Designing and Drafting. It is expected that they will immediately take up their work and organize interesting meetings in this department of the Society's activities.

The speaker of the evening was Mr. Nelson B. Lewis, Chief Engineer of the Board of Estimate and Apportionment, Bureau of Public Improvements, New York City. His address was on the subject of City Planning as an Engineering Problem, and was well illustrated by lantern slides. He pointed out the serious situations which have arisen in several of our large cities because this feature of the city's activities was not given proper consideration. For instance, a street system once established continues almost indefinitely, and therefore should be carefully planned; a street layout and a transportation system are the means by which the people pass from their homes to their work, recreation and amusement, and so should be conveniently arranged. Park and recreation facilities and the importance of the location of public buildings, both with regard to their convenience and appearance were discussed.

Albert E. Thornley,
Corresponding Secretary.

ST. LOUIS, DECEMBER 6

The St. Louis Section participated in a joint meeting of the Associated Engineering Societies of St. Louis, held on December 6, under the auspices of the Engineers' Club of St. Louis. Members and guests were agreeably and instructively entertained by photoplays of unusual merit on the subjects of railroad safety and the evolution of transportation from the time of the squaw with her papoose on her back to the present electrification of the Chicago, Milwaukee and St. Paul Railroad. These were supplemented by a paper on Railroad Trespassing, by A. A. Krause, Commissioner of Safety of the Missouri, Kansas & Texas Railway System.

L. A. Day,
Section Secretary.

ST. LOUIS, DECEMBER 13

The Associated Engineering Societies of St. Louis and the Engineers' Club attended a lecture, dance and luncheon given at the club rooms of The United Railways Company, St. Louis, on the evening of December 13. Mr. A. G. Allan, Assistant Engineer, Valuation Department, Missouri Pacific Railway, spoke on Some Experiences of a Civil Engineer. The talk was non-technical, describing, with a personal touch, peculiar features encountered during twenty years of railroad, canal and reservoir building in the West and was illustrated by lantern slides from photographs of the different classes of construction. Mr. Allan's address was the second one enjoyed by the members of these societies in 1916.

L. A. Day,
Section Secretary.

STUDENT BRANCHES

BUCKNELL UNIVERSITY

A meeting of the Student Branch of Bucknell University held November 6 was the occasion of admitting to active membership in the Branch the Junior Mechanical Engineers. The topic discussed at the meeting was The Function of the Sales Engineer and His Relation to Machine Design, and a paper on that subject was read by Raymond E. Sprenkle; comparing the duties of the sales engineer of the present with the same service as it was in the past, he brought out the opportunity of the sales engineer to study the requirements of the users of machines with a view to discovering what modifications of standard types will be needed to effect an increase in production or decrease in cost of installation, and so meet competition and the conditions presented by novel machinery problems.

The subject was further discussed by Professor Burpee, Mem.Am.Soc.M.E., who developed other possibilities for advancement in the work of the sales engineer.

C. M. Kriner,
Branch Secretary.

CASE SCHOOL OF APPLIED SCIENCE

The Student Branch of the Case School of Applied Science held its regular monthly meeting on December 6. Mr. M. Luckiesh, of the N.E.L.A., gave an interesting talk on the subject of Light, Shade and Color. Mr. Luckiesh as head of the research department of the association has made a marked advance in perfecting lighting facilities. A conspicuous work of his department has been the development of artificial daylight. With the aid of diagrams and illustrations he explained the fundamental theories and practical features of his science, including the importance of color as a factor in better lighting, and emphasizing the prominence of light, shade and color in the arts.

A. Treuhaft,
Branch Secretary.

UNIVERSITY OF CINCINNATI

The meeting held by the Student Branch of the University of Cincinnati on October 20 was the initial meeting for the year 1916-17. Branch President Cowell, presiding, outlined the plans for the coming year, reminding the members to prepare for the Spring Meeting of the Society to be held this year in Cincinnati.

The meeting was addressed by A. J. Baker, Mem.Am.Soc.M.E., who is connected with the sales department of the Cincinnati Milling Machine Company, and who gave an instructive and interesting

forecast of the problems which will confront the engineer at the end of the European war.

Short talks were also given by Prof. A. L. Jenkins and C. A. Joerger, of the University faculty.

EARL A. BOTTS,
Branch Secretary.

UNIVERSITY OF COLORADO

At a meeting of the University of Colorado Student Branch, held November 23, plans were completed for a trip of the members of the Branch to the sugar factory at Longmont, Colorado, which is the third largest factory of its kind in the world and offers many points of interest to the mechanical engineer. A blackboard talk on the general outlay of the plant was given at the meeting and on the 24th the plan was consummated by the trip to the plant

R. F. HAMILTON,
Branch Secretary.

CORNELL UNIVERSITY

The first meeting of the Student Branch of Cornell University was held November 13, at which Prof. Rolla C. Carpenter, Mem.Am.Soc.M.E., Chairman of the Branch, outlined the aims of the Society and the advantages to be gained from membership therein, bringing the student into more intimate touch with engineering practice as it is today, by the presence of prominent engineers at meetings of the Student Branches to present important engineering topics. The meeting was addressed by Professor Jacoby of the College of Civil Engineering of Cornell University, an authority on bridge design, who, in a talk on this subject, discussed the fall of the Quebec Bridge, expressing his opinion that the disaster was due not to any negligence on the part of the engineers in charge, but rather to the fact that the science of engineering was not far enough advanced to insure its success; that the construction of this bridge had been the most gigantic task of its kind ever attempted; the engineers had no precedent to follow and at best their success was only a probability. Officers of the Branch were elected for the year, as follows: Chairman, Professor Carpenter; President, W. C. Bliss; Vice-President, R. O. Compton; Secretary, S. M. Barr, and Treasurer, W. W. Robertson.

S. M. BARR,
Branch Secretary.

UNIVERSITY OF ILLINOIS

An interesting talk on Industry in Bulgaria was a feature at the meeting held November 16 by the Student Branch of the University of Illinois, in which P. Gherganoff, a native of Bulgaria, outlining the geographical formation of that country and its consequent effects on the life of the people, told of their economic products, their travel routes, railroads and the wonderful opportunities for water-power development, which are being readily seized by engineers.

At the meeting held by this Branch on December 7, F. M. Van Deventer gave an illustrated lecture on The Use of Blast Furnace Gas for Power Purposes, comparing blast-furnace gas with producer gas and showing that a large conservation of energy might be effected by the use of blast-furnace gas in boilers and internal combustion engines. The apparatus necessary to prepare the gas for use in engines was shown by lantern slides, as were also the different power units throughout the country where this gas-energy is available, while other slides gave views of the details of large modern internal combustion engines.

V. S. DAY,
Branch President.

KANSAS STATE AGRICULTURAL COLLEGE

The Student Branch of Kansas State Agricultural College held its third regular meeting this season on November 2. Several subjects of interest were discussed, Mr. C. A. Frankenhoff giving a talk on the Utah Copper Company, followed by J. I. Brady, who took up the subject of Ore Treatment by the same company. These were supplemented by A. C. Arnold in a talk on the Shell Plant of the Hart-Parr Company, and the discussions were concluded by E. T. Whitcomb with remarks upon the Manufacture of Shells at the Plant of the Hart-Parr Company.

WM. N. CATOY,
Branch Secretary.

PENNSYLVANIA STATE COLLEGE

The November meeting of the Student Branch of Pennsylvania State College was held on the 27th. R. L. Sackett, Mem.Am.Soc. M.E. and Dean of Engineering of Pennsylvania State College, spoke to the meeting on Power Plants, illustrating his talk by lantern slides showing the ground plans of several plants as well as methods in use for the convenient handling of coal with the greatest saving of time and labor.

The meeting called for a member to represent the Branch at the Annual Meeting of the Society in New York, with the result that Mr. Harry Hammond attended for that purpose.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

About 200 new members were voted into the Student Branch of Massachusetts Institute of Technology at its first business meeting on October 13. There were interesting talks by Prof. E. F. Miller, Mem.Am.Soc.M.E., and honorary chairman of this Branch, Prof. A. E. Norton, Mem.Am.Soc.M.E., Mr. H. L. Coburn, Mem.Am.Soc. M.E., and Mr. J. O. DeWolf, Mem.Am.Soc.M.E. Plans were made for a visit by the members of the Branch to the Waltham Watch Company's plant on October 26.

The first Student Night of this Branch was held November 10, the entire program being carried out by student members of the Society, including a talk by A. E. Keating on an investigation of the efficiency of a boiler plant in Bridgeport, Conn., remarks on engineering opportunities in China by H. C. Ling, and a short account of tunnel construction by W. J. Beadle, based on his work in the New York tubes.

The members of the Branch entertained about twenty guests from the Institute on an excursion to New London, November 11.

EDWARD W. ROUNDS,
Branch Secretary.

PURDUE UNIVERSITY

The meeting held on November 28 by the Student Branch of Purdue University was instructively entertained by motion pictures showing the Indianapolis plant of the Ford Motor Company, which brought out the high efficiency attained by modern labor-saving machinery as applied in the manufacture of Ford cars. Views of safety appliances, schools for the instruction of foreigners and the supervision of foodstuffs supplied to employees emphasized the welfare campaign as conducted at the Ford plant.

G. A. RUESS,
Branch Corresponding Secretary.

WASHINGTON UNIVERSITY

A resumé of an inspection trip to the Ford Motor Company's plant at Detroit, Mich., was the subject at the meeting of the Student Branch of Washington University, St. Louis, Mo., on November 23. The discussion embraced the features of axle design, motor assembly, motor block and testing, commutator and distributor, and observations made at the plant of the Detroit Edison Company on boilers, student members Page, Kurtz, Thumser, Keysor and Conzelman participating in the discussion, after which Prof. F. E. Berger, Mem.Am.Soc.M.E., gave his impressions of the practical instruction of seeing these plants in operation.

WALTER KURTZ,
Branch Secretary.

WORCESTER POLYTECHNIC INSTITUTE

The month of November is reported by the Student Branch of Worcester Polytechnic Institute as having been of great interest.

On November 3, Gershom Smith, vice-president and general manager of the Tabulating Machine Company, of New York, addressed a meeting of the Branch on the subject of cost accounting, explaining the several ways in which shop costs are accounted for, the method of apportioning the burden and the modern system of tabulating cost accounts by machine. To illustrate these points Mr. Smith had on the platform a group of tabulating machines de-

vised and patented by Dr. Hermnn Hollerith, of Washington, D. C., Mem.Am.Soc.M.E.. which were the machines used by Dr. Hollerith in tabulating census returns, and were shown to do very wonderful work, being in use among prominent business concerns, especially the large railroads.

On November 11, by invitation from the parent Society, the members of this Branch attended the submarine exhibition at New London, Conn.

On November 14, Dr. D. S. Jacobus, while in Worcester to attend a meeting of the Worcester Section of the Society, addressed the Student Branch, taking as his subject Some Points Relative to Steam Engineering. The opportunity of meeting Dr. Jacobus was enjoyed by the members of the Branch.

The most important feature of the meeting held by this Branch on December 4 was an instructive talk on the Heat Treatment of Steel, by Chester M. Inman, who discussed the subject from experience gained largely through his two years' connection with the United States Steel Company in Canton, O. At this plant the speaker had been to a considerable extent in charge of certain phases of their heat-treatment work. In showing what was to be expected from certain heat treatment, Mr. Inman explained how such results were gained, why certain qualities in steel were desirable, giving the students the meaning of the terms ferrite, pearlite and cementite and the reasons for their presence, as well as their composition. The results of Mr. Inman's experience in the use of the Shore scleroscope and the Brinell hardness tester were given, as well as some insight into the questions of elastic limits and yield points, with their relation to each other.

H. P. Fairfield,
Branch Corresponding Secretary.

EMPLOYMENT BULLETIN

THE SECRETARY considers it a special obligation and pleasant duty to make the office of the Society the medium for assisting members to secure positions, by putting them in touch with special opportunities for which their training and experience qualify them, and for helping anyone desiring engineering services. The Society acts only as a clearing house in these matters.

POSITIONS AVAILABLE

In forwarding applications, stamps should be enclosed for transmittal to advertisers; applications from non-members should be accompanied by a letter of reference or introduction from a member, such reference letter to be filed with the Society. Copy for notices must be in hand by the 15th of the month.

TECHNICAL GRADUATE, age 30 to 35, practical experience in manufacture and building of steam and hydraulic machinery. Man preferred with wide shop experience, capable of directing men. Location Ohio. Interview arranged only after examination of statement of qualifications, records and compensation expected. 328

LARGE PUBLIC INSTITUTION of middle Northwest seeks services of strictly high class man who can conduct classes and lectures on automobiles. Must be technical graduate with practical experience and not afraid of work. 421.

DESIGNER. Technical graduate. Experienced in design of small intricate machinery. Location New York. 424

ENGINEER who combines faculty for writing logical interesting technical reports with ability to turn these into reliable newspaper stories. Single, age about 30. Technical education. Experience in building construction and if possible general knowledge of power-plant engineering. Demonstrated ability as writer displayed through editorial and similar work. Name confidential. 594.

INSTRUCTORS for school of mechanical trades in Iowa. Salaries $1,000 to $1,200 per year; promotion dependent to large extent upon commercial work which can be turned out during the year.

(*a*) Energetic young man with some business ability to take charge of automobile department; must know his subject thoroughly as department is doing large repair business, and must be able to build up department educationally and commercially. Competent to teach in automobile lines, including electric cranking, lighting, and ignition course, be able to organize material and work in such way that maximum number of students can be handled with minimum teaching force and expense.

(*b*) Man to handle foundry and machine shop and possibly forge. 676.

PUBLICITY ENGINEER to take charge of firm's publication and write all advertising copy. State age, experience and salary expected. Location Illinois. 687

YOUNG ENGINEERS, experienced in manufacture and analysis of metals. Salaries $65 and $80 per month to start. Location New Jersey. 689

DRAFTSMEN with experience on electric traveling cranes. Permanent employment and good wages to competent men. Location Ohio. Apply by letter. 693

EXPERIENCED DRAFTSMAN on water-tube boiler work as detailer and designer. $1,200 to $1,500. Permanent position and good prospects for right man. Location Pennsylvania. 695

ASSISTANT TO MANUFACTURING EXECUTIVE. Mechanical engineer. Must show successful experience in same line of work, and also speed, energy, endurance, initiative, aggressiveness, courage, accuracy, memory, good judgment, strong sense of propriety. Location Detroit. Name confidential. 696

ESTIMATING ENGINEER. Engineering and estimating experience required as involved in formulating selling prices and calculation of proper size of steam, gas, pumping engines, air and gas compressors and heavy special machinery. Technically trained man desired. Give experience, references and salary desired. All correspondence strictly confidential. Location Ohio. 697

SUPERINTENDENT for large manufacturing plant. Must be familiar with manufacturing methods for producing small interchangeable parts of brass, steel, and iron. State age, education, experience and salary desired. 699.

REPRESENTATIVE for large concern manufacturing one type of machine tool, to work in conjunction with agents. Previous selling experience not necessary. Good mechanical ability most desirable. Should be about 30 and have had mechanical training in conjunction with wide shop experience and should possess knowledge of best practice in machine tool uses. Location Ohio. 706.

YOUNG ENGINEER with some office and shop training for position as confidential man in office. Will have charge of various cost price and engineering records and assist in oversight of engineering salesmen, to eventually work into considerable amount of sales engineering correspondence. Location Detroit, Mich. 712.

LARGE EUROPEAN COMPANY requires machine-tool salesman speaking French, Italian or Russian, with practical experience, to assist in purchasing machine tools in United States. Suitable man would later be required to reside abroad. Apply by letter. 715.

DESIGNER. Engineering graduate, with experience in automatic machinery. Good opportunity to clever man. State education, experience, and salary expected. Location New Jersey. 717.

DRAFTSMAN. Permanent positions for high-grade men. Location Plainfield, N. J. 719.

CHIEF ENGINEER OF STEAM PLANT of 10,000-kw. capacity (turbine plant). Willing to pay for high-grade engineer. Location Pennsylvania. 721.

YOUNG ENGINEERS on power-plant operation and testing. Apply by letter. Location New Jersey. 722.

MACHINERY SALESMAN, salary and commission, with guarantee of $150 per month. Experienced in boiler and power-plant work. Location New York. 723.

MECHANICAL ENGINEER, with several years mechanical experience, for investigating mechanical operations and equipment and developing new apparatus in connection with operations of large industrial concern. High-grade man desired. In first letter state age, experience and training. Location New Jersey. 724.

COMBUSTION ENGINEER experienced in hand and stoker firing of bituminous coal, for studying boiler efficiency and other combustion problems. High grade man desired. Location New Jersey. 725.

DRAFTSMEN. For large rubber concern in Ohio, number of competent draftsmen on machinery layouts, piping and electric wiring. Also two tracers and a checker. Location Ohio. 727.

PRODUCTION AND PLANT EFFICIENCY WORK. Technical graduates. Preferably two or three years' experience. Must be capable, wide-awake and want to make good. Well established company. Location Indiana. Unusual opportunity for several men of ability to work into organization. 728.

MECHANICAL DRAFTSMAN, with about six years experience in detailing machinery. Location New Jersey. 729.

MECHANICAL ENGINEER who would be interested in partnership in established business dealing largely in apparatus pertaining to economical production of steam, as recording instruments, steam meters, water meters, calorimeters for fuels and gases, etc. Headquarters New York. 736.

EDITORIAL ASSISTANT for technical paper. Location New York. Salary $30. 738.

YOUNG ENGINEER as salesman, for mechanical apparatus, forgings, castings, etc. Salary $25-$30. Location New York. 740.

ENGINEER for American plant in Hayti, to take charge of engines, boilers and pumps. Should be familiar with d-c. installation for lighting plant. Salary $150 to $175 per month. Will pay traveling expenses, board allowance, and after six months service entitled to return expenses. 742.

ASSISTANT ENGINEERS, familiar with power-station and factory-construction work. Location Connecticut. 743.

PRACTICAL MANUFACTURING EXECUTIVE, accustomed to supervising quantity production on modern basis, preferably of machine parts and stampings, and with some technical and construction experience; man from 30 to 35 years of age. Willing to join a large organization at salary of about $2000, as utility man and candidate for future position of more importance as opening arises. Location East. 746.

DRAFTSMAN familiar with thresher, gas and steam tractors. Give experience, age and salary desired. Location Ohio. 749.

MEN AVAILABLE

Only members of the Society are listed in the published notices in this section. Copy for notices should be in hand by the 15th of the month, and the form of the notice should be such that the initial words indicate the classification. Notices are not repeated in consecutive issues.

MECHANICAL ENGINEER, technically educated, twenty years experience in shop and drawing office, railroad and general contract engineering. Desires to make a change. Location immaterial. At present employed. Salary $2400. A-1

MECHANICAL ENGINEER. Twenty years experience in practical management of power-plant equipment; 15 years as executive. Broad experience with steam, electrical, hydraulic and refrigerating machinery. At present chief engineer and superintendent of maintenance for large industrial plant. Desires to connect with large concern wanting to improve conditions. Minimum salary $2500. A-2

ASSISTANT TO EXECUTIVE or EXPERIMENTAL ENGINEER. Stevens 1911 graduate; married; age 28. Possesses energy, initiative, self-confidence. Last three years in Middle-West in natural-gas transportation and measurement, including successful experimental work. Temporary engagement with U. S. Bureau of Mines about to end. Desires position with large industrial or engineering concern offering permanency and future. Initial salary not primary consideration. A-3

ASSISTANT MECHANICAL ENGINEER. Jun. Am. Soc. M. E., Cornell M.E. graduate; age 28. Has had considerable drafting-room experience, and at present employed with large coal-mining company but desires to make change. For last three years experience chiefly confined to power plants and testing power-plant equipment. Location preferred, New York. A-4

RAILWAY MECHANICAL ENGINEER, age 37, technical education, seventeen years experience, as railway machinist, draftsman, chief draftsman and mechanical engineer. Desires position with railway company, railway-supply house or industrial plant, with greater responsibility and opportunity. Location immaterial. At present employed. Salary $2100. A-5

FUEL TESTING ENGINEER. Graduate; age 34. Seven and a half years experience in scientific testing of coal in industrial plants, for large coal company in Middle West. Desires position as combustion engineer for large user of coal. At present employed. A-6

SALES ENGINEER. Graduate. Experienced in scientific testing and selling of coal. Desires position as sales manager for coal-operating company. At present employed. A-7

CHIEF DRAFTSMAN or ASSISTANT SUPERINTENDENT. Technical graduate; age 36. Thirteen years experience. Familiar with manufacture of water-gas, soaps, leather belting, coal-mining and handling machinery. At present employed. Salary $1800 to $2400. A-8

DRAFTSMAN. Age 25. Three years technical training. Three years shop practice. Two years experience on design of appliances for installation of steam, gas, air, water and oil. Familiar with production work. Desires position with future. A-9

EXECUTIVE ENGINEER. Age 33. Ten years in responsible charge of important work; estimating, designing and constructing systems for the technical handling of all kinds of material in course of manufacture; six years in present position. A-10

ENGINEER OF TOOLS AND METHODS, SUPERVISOR OF PRODUCTION, CHIEF DRAFTSMAN or ASSISTANT SUPERINTENDENT. Member wishes to correspond with well-established concern. Wide experience in several of the largest and best-known concerns in this country and Europe, manufacturing small and medium-size accurate interchangeable parts, such as adding machines, typewriters, cash registers, watches and electrical mechanism. Natural mechanical and executive ability, together with broad experience in developing production of above work. Location, Chicago or vicinity preferred. A-11

WORKS MANAGER, SUPERINTENDENT or PLANT ENGINEER. Graduate mechanical engineer. Good organizer and executive. Extensive experience in the management of mechanical departments of railroad, coal-mining and industrial corporations; design, construction and management of large steam and electric power plants; design, construction, and maintenance of industrial plant buildings; reinforced concrete; design, installation, and maintenance of heavy and light steam, hydraulic and electrically driven machinery; management of shop, yard, office and drafting room forces. A-12

MECHANICAL ENGINEER. Technical graduate; age 26; two years experience operating and maintaining large power plant for industrial company and two years in efficiency, time-study and production end of same concern. Desires position with responsible future. Location New Jersey or Pennsylvania. A-13

MANAGER, WORKS MANAGER, or GENERAL SUPERINTENDENT. Technical education, M.E. Good executive abilities. Over 25 years abroad and varied experience in heavy, medium (electrical and metal working), small and interchangeable work; thorough in modern methods, and practical along all departments, machine shop, smith, foundry, plating, japanning, wood-working, etc. Thoroughly capable in shop organization and supervision of manufacturing; qualified in office, buying, sales, cost, piece, bonus or premium methods. A-14

DESIGNING or CONSTRUCTING ENGINEER desires to change. Wide experience in power- and industrial-plant, pumping-station design and construction. Salary $4200 or salary and fees. A-15

ASSISTANT SUPERINTENDENT. Graduate M.E. Capable machinist. Familiar with scientific shop management and can produce results in handling men. A-16

MACHINE DESIGNER. Technical graduate. Seventeen years experience on centrifugal pumps, steam engines, steam pumps, elevating and conveying machinery, ball-bearing manufacture, roofing paper and paper machinery, factory equipment and maintenance. Now holding position as chief draftsman and engineer. Desires responsible position. Location Boston or vicinity preferred. A-17

MECHANICAL ENGINEER at present in executive position with large construction company, seeks connection with industrial or contracting concern near New York. Proven ability to handle general problems as well as details of technical or business nature. Familiarity with costs and prices qualify for position of responsibility. A-18

MECHANICAL ENGINEER. American; technical graduate 1902. Thoroughly familiar with manufacture and sale of high-grade engineering specialties. Factory experience in pattern, foundry, machine shop and drafting departments. Theoretical and practical experience of 16 years. A-19

HEATING AND VENTILATING ENGINEER. Age 35, married. Graduate M.E. from prominent university. Six years experience in estimating and designing heating and ventilating systems, covering wide range of installations. Desires permanent and responsible position. Available about January 1. A-20

CHIEF DRAFTSMAN, MECHANICAL ENGINEER, COMPETENT EXECUTIVE, systematic and reliable; has originality and initiative; 15 years experience. A-21

MECHANICAL ENGINEER. Jun.Am.Soc.M.E. Cornell graduate; age 28. Six years experience on power plant testing and supervision, and some selling experience. At present employed. Location preferred, New York or vicinity. A-22

TECHNICAL ENGINEERING EXECUTIVE. Age 34, married. Nine years practical experience as production engineer and executive. Good organizer, hustler, keen observer, energetic; has originality and initiative; up-to-date in costs, efficiency engineering, factory management, etc. Desires change with greater opportunities. Location immaterial, if healthy. A-23

MECHANICAL ENGINEER, MAINTENANCE ENGINEER, MASTER MECHANIC. Graduate; age 33; married. Thirteen years experience in Germany, England and United States, steam and electrical plants, heating and ventilating, factory layout and equipment, labor-saving devices, construction and maintenance, systematic. Desires permanent responsible post. A-24

WORKS MANAGER. Twenty years experience in manufacturing typewriters, firearms, automobiles and power-house equipment. A-25

EXPERIENCED ENGINEER on dies, jigs, fixtures and special machines for metal-working purposes is open for position. Chicago district preferred. A-26

MECHANICAL ENGINEER. Graduate from prominent university. Valuable and wide experience in shop, office and field both as subordinate and executive; five years in sales and consulting capacity with present connection. Desires responsible position in executive offices of good, live, progressive concern. A-27

MECHANICAL ENGINEER, ASSISTANT TO WORKS MANAGER or SUPERINTENDENT. Assoc-Mem.Am.Soc.M.E. Graduate Cornell University; age 31. Eight years experience in shop and drafting room. Accustomed to dealing with men. Aggressive, and eager for responsibility. Wishes larger opportunity than present position affords. Best references. Eastern states preferred. A-28

MECHANICAL ENGINEER. Age 33. Specialties: shop- and power-plant construction, including installation of buildings, foundations, machinery and electrical apparatus; also crude-oil burning, valuation engineering and railroad mechanical engineering. A-29

TECHNICAL GRADUATE, eight years experience heat-treating, forging, testing and metallographic study of steel and brass. A-30

WORKS MANAGER or GENERAL SUPERINTENDENT. Age 40. High grade man open for new position. Able executive, good mechanic, with thorough practical knowledge of labor, production methods, planning and conditions necessary for economical factory management. Excellent past record. A-31

SUPERINTENDENT, SALES ENGINEER or ASSISTANT TO EXECUTIVE. Assoc-Mem.Am.Soc.M.E. Age 35. Fifteen years experience in manufacture and sale of electrical machinery. Desires change. Available upon 30 days notice. A-32

MECHANICAL ENGINEER or ASSISTANT SUPERINTENDENT. Assoc.-Mem.Am.Soc.M.E. Technical training, shop experience, 10 years of design and experimental work on gas, oil engines and air compressors. Able to ferret out and correct vexing problems about a shop, and estimate costs. Middle West preferred. A-33

EXECUTIVE, MANAGER IN ORGANIZATION WORK. Fellow A.I.E.E., Member of The Franklin Institute. Broad business experience and technical training; familiar with shop practice, cost, productive systems and sales engineering; operation of power wagons; also design, construction and purchase. A-34

ASSISTANT TO SALES MANAGER. Assoc-Mem.Am.Soc.M.E. Graduate M. E. Age 34, married. Desires position as assistant to executive or sales manager or as advertising manager. Several years advertising and editorial experience in power plant, mining and contracting fields. Very little actual selling experience. Good correspondent. Tactful. Accustomed to responsibility. East preferred. At present employed. A-35

MECHANICAL ENGINEER, graduating from well-known university in February, desires position with future. Any location. References and experience given. A-36

INDUSTRIAL ENGINEER. Technical graduate, Junior Member, age 29. Three years' experience as designing draftsman of industrial plants, transmission machinery and labor-saving devices. Past two years industrial engineer, experienced on time-study work, scheduling, modern cost system, accounting, etc. Ability to increase production and decrease costs, standardize equipment and methods of manufacture. A-37

INDUSTRIAL ENGINEER. Associate-Member. Pulp and paper mills (specialty newsprint). Fourteen years' experience in design, supervising, complete layouts, purchasing, construction, operating and maintenance. Executive capacity. A-38

GAS ENGINE ENGINEER. Technical man. Eight years' experience in design, development, and production of stationary engines and aeronautical motors. Desires position requiring unusual executive ability and judgment. A-39

ENGINEERING EXECUTIVE. Graduate M.E.; age 36; married. Good executive and organizer. General business training as executive in purchasing, selling and manufacturing departments, having filled positions of purchasing agent, branch sales manager, and plant manager, the latter for several years. Thoroughly familiar with modern manufacturing methods, efficiency systems and cost accounting. Prefers position which would ultimately lead to an officer and part owner or partner in the business. A-40

YOUNG ENGINEER, TECHNICAL GRADUATE, with two years' good engineering experience desires position as mechanical engineer or in engineering sales. At present employed. A-41.

MASTER MECHANIC OR CHIEF DRAFTSMAN. Ten years' experience in the manufacture of interchangeable parts. Thoroughly experienced in design of jigs, tools, fixtures and special automatic machinery for manufacturing parts on interchangeable basis to close limits. Location preferred in (or in vicinity of) New York or Newark, N. J. A-42.

ASSISTANT TO EXECUTIVE OR CONSULTING ENGINEER. Associate member, technical graduate, age 28. Ten years' practical experience, embracing machine and plate shops, drafting, inspecting, estimating, production and supervision. At present assistant superintendent of manufacturing plant employing 350. Location in vicinity of New York preferred. Salary $2000. A-43.

WORKS MANAGER, CHIEF ENGINEER OR GENERAL SUPERINTENDENT. American, 44 years of age, with 18 years' practical executive experience in the positions of chief draftsman, general superintendent and works manager on light and medium-heavy interchangeable parts as used on typewriters, moving-picture machines, gasoline and electric auto trucks, water meters, linotype machines, automatic machinery and machine tools, etc. Desires to make a change on or about May or June, 1917. For the past five years and at present successfully engaged as general superintendent with a manufacturing concern making machine tools. Desires to locate within a radius of 100 miles from New York City. A-1 systematizer, organizer and production man, with excellent executive ability, and can produce results. Best of references from past and present employers as to integrity, honesty and ability. Salary, $4000 per annum. A-44.

ENGINEER. Eighteen years' experience, covering shop management, sales and development work, principally in connection with pneumatic appliances. Seeks executive position. A-45.

INDUSTRIAL PLANT EXECUTIVE. General experience as engineer, purchasing agent, and cost accountant in large industrial plant. Available on short notice. Present location New York. A-46

MANAGER. Mechanical Engineer, 35, technical graduate. Eleven years' thorough manufacturing experience in both office and shop, including sales and organizing cost, production, bonus and piece-rate departments, principally on light machinery, small tools and interchangeable parts. Can handle men successfully, lower costs and maintain quality. Salary $5000. A-47.

ENGINEER. Specialist and recognized expert in public-utility and industrial power work offers full or part time services to firm or corporation interested in such properties. Broad experience in the design, construction and operation of power systems and in making investigations, valuations and reports covering going and projected enterprises. A-48.

PRESENTATION OF THE JOHN FRITZ MEDAL

THE John Fritz Medal was presented to Prof. Elihu Thomson, eminent electrical engineer, for "achievements in electrical inventions, in electrical engineering, and in industrial development, and in scientific research," in the Central Hall of the Massachusetts Institute of Technology, on the evening of Friday, December 8, 1916.

The meeting was called to order by Prof. Albert Sauveur, Chairman of the John Fritz Medal Board of Award, and the program of the evening included addresses by John J. Carty, Chairman of the Presentation Committee of the John Fritz Medal Board of Award: E. W. Rice, Jr., President of the General Electric Company, and Dr. Richard C. Maclaurin, President of Massachusetts Institute of Technology. The presentation was made by Dr. Charles Warren Hunt, Past-Chairman of the Board of Award, and the ceremonies concluded with a response by Dr. Thomson.

Mr. Carty reviewed the history of the John Fritz Medal, described the manner of awarding it and enumerated the distinguished men to whom this award has already been made.

Mr. Rice, a life-long friend of Professor Thomson, and with an intimate knowledge of his work, delivered a very interesting and forceful address. As emphasizing the magnitude of Professor Thomson's inventive work, Mr. Rice said:

"It would be impossible in the brief time at our disposal to adequately describe the achievements of our medalist in these various fields as it would involve describing the life work of one of the world's most prolific and industrious inventors and scientists. The impossibility of performing such a task can perhaps best be indicated by the statement that in the field of electrical inventions alone Profressor Thomson has been awarded something over 550 U. S. Patents, and in other fields, notably mechanical work, about 150 patents: that he has made contributions to the world's scientific and technical literature set forth in several hundred articles describing not only his own discoveries and inventions but making remarkably interesting contributions to scientific speculation and thought."

ELIHU THOMSON

The speaker also gave testimony to the profundity of Professor Thomson's scientific knowledge:

"As a close observer of Professor Thomson's activities for over 36 years, I may be able to say something of interest as to his method of work. A skilled workman, he is always able to himself do the work which he asks others to perform. He prefers to make his own drawings, freehand sketches, to which he adds dimensions and a short written description. He selects his own materials, supervises the work, quickly makes such modifications as may be needed during its progress and stands constantly ready to give just the advice necessary to help over difficult places and turn failure into success. His inventions are the result of such profound and accurate knowledge and developed with such skill that they almost invariably work on the first trial in accordance with expectation. One of the most extraordinary things about his experimental work is its low cost. I am sure that if a prize were to be given for the inventor or engineer who could make a dollar go the furthest and produce the greatest results that Professor Thomson would have no worthy competitor in this or any other country. And I say this feelingly because I have had some experience with other inventors. He seems to possess an almost intuitive insight into Nature and her ways, probably because of the quickness and accuracy of his perception combined with the most remarkable depth and range of scientific knowledge, all helped by a marvellously retentive memory. In fact Professor Thomson perhaps more than any other inventor since the days of Henry or Faraday, combines in his person profound and accurate scientific knowledge with extraordinary technical skill."

Dr. Maclaurin characterized Dr. Thomson as an educational force of great potency and a man whose merits should, in the very highest interests of education, be widely appreciated and acclaimed. He gave an interesting conception of the mentality of such a man as Dr. Thomson:

"It has sometimes seemed to me that not the least significant fact in regard to Professor Thomson's work is the fact, known to those who have had the pleasure of seeing him in his home, that his laboratory is built right into the home and is an integral part of it. Probably thoughts on scientific problems are never wholly absent from his mind, although he may be consciously thinking of quite other matters. It can hardly be necessary to say that a man who has achieved what Thomson has done must be more than an unselfish, generous, well-trained, well-rounded, well-balanced man of science. Above all and pervading all must be imagination, not necessarily the imagination of a poet, but something akin to that in quality and in power, and it is of course mainly because Thomson is a man of imagination in the highest sense that he has achieved so much success and earned so much respect, not only in this country but throughout the scientific world. He has been literally showered with honors and it must be almost a unique thing to obtain two great national medals within almost a week, one from the Royal Society of London, and the other the great honor of the Fritz Medal that is now to be awarded. I heartily congratulate the Board of Awards on having found a man worthy to be placed beside the greatest whose names have already given dictinction

to their selection like Graham Bell, Edison and Kelvin. Such a one undoubtedly is Elihu Thomson.

Past-Presidents Visiting China

Dr. John A. Brashear, Mr. Ambrose Swasey and Mr. John R. Freeman, all past-presidents of The American Society of Mechanical Engineers, sailed from Vancouver on December 20 on an extended tour of the Orient to inspect engineering work there and also to enable Dr. Brashear to learn more about the educational system in that part of the world.

The tour is the climax of probably one of the most notable birthdays in the career of Dr. Brashear. On Wednesday, November 22, Pittsburgh friends of the Doctor planned a great public reception to him, and two days later "Brashear Day" was observed in that city and all Pittsburgh was given the opportunity of contributing to a fund for purchasing and endowing the old Brashear home and workshop in Holt Street. Commenting on the tour, the *Pittsburgh Sun* said editorially:

IT IS NEVER TOO LATE

Dr. John A. Brashear—and the name is enough of an introduction—will arrive at the 76th milepost on his journey through life on November 24th. This represents at least 70 years of activity, of dreams, of ambitions, of hopes realized and of disappointments that were unavoidable; of elation at success and depression at failure; of happiness and of sorrow. But through them all the beloved doctor has not allowed the big things to crowd out of his life the little ones, and by so doing he has retained constant interest in the things that have been going on around him. He has remained young in mind and body, and today he is physically and mentally more vigorous than two-thirds of those who claim a corresponding number of years.

But the point of this is that on his birthday Dr. Brashear will leave for a tour of the Orient. He will study the educational problem as it is presented in the Philippines, Japan and China. Accompanying him will be two well-known men, one skilled in Oriental affairs and the other, like the doctor, a maker of astronomical instruments. The tour outlined is a comprehensive one and will give the travelers a broad view of the Orient, and the exceptional opportunities for investigation that will be afforded them will be ample.

The action of Dr. Brashear in undertaking this long journey, principally for pleasure, to be sure, but also for study, affords the average individual food for thought. It is never too late to undertake anything that promises to redound to the benefit of humanity, no matter in how small a degree. Some persons might be inclined to think that after one has passed the Biblical span he is justified in taking a rest. But not so with energetic and youthful Dr. Brashear. He wants to know about the educational system of the Orient. What he sees there might result in an improvement in this country, and so he joins two congenial companions and starts. He will return even a better man than when he left because his mind will have become enriched by what he has seen and by the persons with whom he has talked and Pittsburgh will get the benefit. It is a wonderful thing to be able to carry 76 years as easily as does Dr. Brashear.

Mr. Swasey, in his characteristically painstaking manner, prepared in advance the complete itinerary of this tour, from the time of Dr. Brashear's leaving Pittsburgh on November 24 and his own departure from Cleveland on the same date, to the party's arrival back at San Francisco on April 2, 1917, after their journey to Yokohama, Kobe, Peking, Hankow, Nanking, Shanghai, and Hong Kong, and supplemented this with a map showing the route of the trip.

Mr. Freeman is accompanied by his two sons, John R. Freeman, Jr., a recent graduate in electrochemical engineering, and Hovey T. Freeman, a recent graduate in mechanical engineering from the Massachusetts Institute of Technology.

American Uniform Boiler Code Congress

The work of the Boiler Code Committee received marked impetus from the action of the American Uniform Boiler Code Congress held at Washington, D. C., on Monday and Tuesday, December 4 and 5, 1916. The Congress was a gathering of representatives of various states interested in a uniform boiler code, which was called by the Industrial Commission of the State of Ohio, the body having charge of boiler regulation in that State. Representatives were sent by the Governors of 28 states, which, with the representatives of boiler-making, boiler insurance and other interests, numbered some 70-odd attendants. Hon. J. C. Callery, Chief Deputy, Division of Boiler Inspection, State of Ohio, presided.

The program began with an address by Hon. T. J. Duffy, member of the Industrial Commission of Ohio, who brought out forcibly the obligation of the Government to guard its citizens against the avoidable hazards of industry, pre-eminent of which is the use of magazines of energy like steam boilers, and the desirability of uniformity in the regulations adopted to this end.

He was followed by Dr. F. R. Hutton, Mem.Am.Soc.M.E., professor emeritus at Columbia University and vice-president of the American Museum of Safety, whose topic was Civilization and Government Are Based on Human Life; Protection of Life Is a Government's First Duty. Professor Hutton spoke of the importance to the mechanical engineer of safety considerations, and he showed how the mechanical engineer is best fitted to make provisions for the safety of the public. He alone can pass on the advantages or disadvantages of special constructions and his recommendations may safely be trusted. The mechanical engineer has become a leader whom we cannot afford to disregard, and safety standards proposed by him may be accepted as authentic.

The speaker stood "for the proposition that an industrial accident (and a boiler rupture or failure is such an accident) is an economic loss and an indefensible blunder from which the community has a right to be defended, and by ordinance or legislation." He showed that a boiler accident entails a loss in five different directions and explained that these are all capable of being expressed in dollars, aside from the bereavement in fatalities and the suffering inseparable from such disasters. From this he showed that the safeguarding of human life against boiler accident by legislation and ordinance is in line with progress and development, and he showed that scientific knowledge has advanced to a point where safety can be attained and that there remains only the question of proper legislative channels. Now the legislative and executive arms of the government should take hold with a strong hand to correct and remove the fatal conditions. It has been made clear that the facts and laws of applied science in respect to stresses and safety in pressure resisting vessels have been codified and recorded, and a way pointed out whereby uniformity of standard in the various states of the Union may be secured.

The second session opened with an address from Hon. P. J. McBride, Commissioner of Labor of Kansas, on The Protection of Labor as a Human Necessity and Its Effect on Business Economy. Mr. McBride emphasized the importance

of greater attention to the safety of boilers and their appurtenances as an element in the industrial development of the nation.

Next, Prof. L. P. Breckenridge, Mem.Am.Soc.M.E., of Sheffield Scientific School, Yale University, spoke interestingly on Civil Service in the Department of Boiler Inspection. He pointed out the importance of absolutely divorcing this department from politics, and showed how the civil service could best handle the examinations and appointments of the boiler inspectors. He referred to the A.S.M.E. Boiler Code as a set of boiler-construction rules that should be generally applicable in all states, and he made a plea for uniformity throughout. He produced statistics showing that in 1914 there were in the whole German Empire 8 boiler explosions—the same number that Mr. McBride had just admitted having in the State of Kansas in 10 months. In the United States in the same year there were 575 explosions; in Germany the loss of life was 2, in the United States 30; in Germany the personal injuries 7, in the United States 176.

S. F. Jeter, Mem.Am.Soc.M.E., accredited representative of the State of Connecticut, read a letter from Governor Holcomb expressing his belief in the desirability of uniformity of laws covering similar commodities in different states and advising of his interest in the movement embraced in the Boiler Code Congress.

J. C. McCabe, Mem.Am.Soc.M.E., chief inspector of the City of Detroit, Mich., spoke on Realizations of a Uniform Boiler Code. He first showed clearly the hardship that is now imposed on both builders and purchasers of boilers by the numerous different codes and pointed out how necessary is this movement toward uniformity in construction codes. Mr. McCabe made a strong plea for a single uniform code, urged all states that have different codes to coöperate with the various states that have adopted, or are about to adopt, the A.S.M.E. Code, and announced that the State of Michigan would adopt that code this winter.

Mr. Callery announced that his State, which has in effect been working under two different boiler codes, is about to adopt the A.S.M.E. Boiler Code as its standard.

Hon. Victor T. Noonan, safety director of the Industrial Commission of Ohio, who was slated at the Tuesday morning session for an address on Some Interesting Aspects of Accident Prevention, was unable to be present and the time was occupied in general discussion. Thomas C. Eipper, deputy commissioiner of the Department of Labor of the State of New York and connected with the Bureau of Industrial Code, said that the bureau had the A.S.M.E. Code under favorable consideration. The possibility of Federal supervision of boilers transported from one state to another was suggested.

Henry Hess, chairman of the Standardization Committee of the A.S.M.E. and a member of the governing Council of that society, read a paper telling of the genesis and history of the A.S.M.E. Boiler Code. In Mr. Hess' address, the announcement was made that in the future, every state and municipality that adopts the A.S.M.E. Boiler Code shall be entitled to have a representative present at all meetings of the Boiler Code Committee.

Hon. Edward N. Hurley, chairman of the Federal Trade Commission, read a paper on Standardization as the Foreword of Business Efficiency. John A. Stevens, chairman of the Boiler-Code Committee of the A.S.M.E., told of the manner of production of the A.S.M.E. Code and the care which had been taken to have all interested parties have a voice in its formation.

The following resolution was unanimously adopted, only those having credentials from state or municipal executives being allowed to vote:

Whereas, Industry in every line of endeavor is very closely associated with steam as a motive power and the use of steam boilers; and

Whereas, Obtainable statstics covering a period of years show that in the United States there is annually a loss of from 400 to 500 lives and the disablement of from 1,000 to 3,000 people due to explosions of steam boilers; and

Whereas, The Government has recognized in the effort it has put forth in the safety movement that its first duty is the protection and safety of human life; and

Whereas, The Federal Government where it has the jurisdiction has prescribed rules for the construction of steam boilers; therefore, be it

Resolved, That it is the sense of this congress that all states should exercise supervision over the manufacture and use of steam boilers and all pressure vessels.

Mrs. Helen Adelaide Goldsmith (appointed by Mayor Gearon as delegate from Chicago) read an address commending the work of the A.S.M.E. and urging the yielding of the more sedentary occupations to the women, while the men occupy themselves with the more active work of the world. William F. Keisel, Jr., Mem.Am.Soc.M.E., assistant mechanical engineer, Pennsylvania R. R., said that the railroads had interested themselves in the framing of the Code and were in favor of its adoption. Reports were heard from committees on legislation, boiler codes, interchangeability of inspectors, etc., and resolution of thanks to the Ohio Industrial Commission and to Thomas E. Durban, chairman of the American Uniform Boiler Law Society were adopted.

Sixty-Ninth Meeting of A. A. A. S.

THE American Association for the Advancement of Science and the national scientific societies which have arisen from it and retain affiliation with it, have been important factors in encouraging scientific research and diffusing general interests in its results. The Association is organized in 12 sections covering the field of pure and applied sciences. Section D is the Engineering Section, of which Prof. A. H. Blanchard, of Columbia University, is Secretary. Our Society is affiliated with the Association and is represented on its Council by Dr. D. S. Jacobus and Mr. Wm. B. Jackson.

The Association held its sixty-ninth meeting in New York City from December 26 to 30, 1916. The membership of the Association at present numbers about 11,000, and it is believed that this meeting was the largest and most important gathering of scientific men hitherto held in this country or elsewhere. All the affiliated societies joined with the Association in this convention, and this year there were, including the sections of the Association, more than 50 separate national bodies meeting together.

Section D, Engineering, held a session in the Engineering Societies Building on the invitation of The American Society of Civil Engineers, The American Institute of Electrical Engineers, The American Institute of Mining Engineers and The American Society of Mechanical Engineers. At this meeting Dr. Bion J. Arnold gave the address of the retiring chairman and there were addresses by representatives of the national engineering societies, including President Hollis of our Society, followed by a reception to engineers and their associates.

Section D also held a joint session in the Assembly Hall of the Automobile Club of America with the National Highways Association, The Automobile Club of America, and the National Automobile Chamber of Commerce.

ENGINEERING SURVEY

A Review of Engineering Publications in All Languages. All the leading periodicals of the engineering world, embracing over 1000 different publications, are received at the Library. These are systematically examined for review each month in the Survey.

SUBJECTS OF ABSTRACTS

In this issue. Section Aeronautics. we publish a list given out by Lieut-Col. Geo. O. Squier. Aviation Service. War Department. U. S. A.. embodying some of the problems connected with the development of military aviation and aerostation. This list is well worth attention. both because of its source and the evident carefulness with which it has been thought out.

The publication of this list is the beginning of an effort on the part of The Journal to cover the development of engineering research in the process of evolution. as distinct from abstracts of results previously published in other periodicals.

THIS MONTH'S ARTICLES

H. L. Horning compares truck and tractor engines. and discusses the characteristic curves of such engines, as well as the important but comparatively neglected subjects of water pumps and engine cooling.

Methods of comparing automobile performance are discussed by W. Fishleigh. who. among other things, presents a simple formula for the "automobile performance factor," which. the writer contends. affords a valuable comparison for cars.

In a paper before the Philadelphia Section of the S. A. E.. John Younger. Mem.Am.Soc.M.E.. presents the theory of retardation as applied to motor cars. In the discussion of this paper, the speaker made an important statement. viz., that the time is coming when local authorities will have to submit brakes to a regular system of inspection as a means of insuring the safety of travel on public roads.

In the Section Engineering Materials is reported a paper on testing steel by alternating stresses. the author using a method substantially different from that of Bauschinger. It appears to be possible to find the stress which a given sample of steel is capable of sustaining for an unlimited number of reversals without damage; this can be done by "static" tests of the kind described. which have a further merit of quickness as compared with endurance tests carried to destruction.

In the same section will be found another paper on steel. this time on the annealing of carbon steels as affected by small changes of temperature and by magnetic fluxes acting separately or simultaneously. Among other things. the writer describes an electromagnetic method whereby the critical point of a piece of steel under heat treatment can be determined directly and accurately. This method. especially in the case of low-carbon steel. proved to be of higher sensitiveness than the thermoelectric method.

Modern methods of heat treatment as applied at an American plant are described in an abstract taken from *The Iron Trade Review*.

Data of tests on the tensile strength of asbestos rope when exposed to fire have been obtained experimentally in the mechanical laboratory of the Tomsk Institute of Technology. in Siberia. Russia. They show that on the whole. if used as life lines at fires. asbestos ropes present no material advantage as compared with ordinary hemp rope.

Some minute reactions in the combustion of wood are described by James Scott, whose investigations of similar reactions in the case of rusting of iron and paints on metal have been reported in previous issues.

That ignition of explosive gas mixtures by electric sparks is essentially a phenomenon of ionization. and does not depend exclusively on either temperature or voltage in the spark gap. is the contention of J. B. Morgan.

From *Power* is briefly abstracted the description of a new internal-combustion engine. Its cycle diagram is reproduced and explained.

In the section Mechanics will be found a brief reference to an article by Prof. A. Stodola on the critical speed of shafts. A more complete abstract of the same article will be given in an early issue.

Safety devices for preventing explosions in gas-firing installations on steam boilers are described from data published in a German periodical.

Aeronautics

SCIENTIFIC RESEARCH FOR NATIONAL DEFENSE AS ILLUSTRATED BY THE PROBLEMS OF AERONAUTICS, Lieut-Col. Geo. O. Squier

The following are some of the present problems connected with the development of Military Aviation and Aerostation.

I AERODYNAMICS

a Continue the development of the mathematical theory to explain the phenomena recorded in the aerodynamical laboratories, and to forecast further results.

b Obtain solutions for the speed and direction of flow of air about geometric and aerotechnic forms, and develop experimental means to visualize or map the speed and direction of flow.

c Map the currents of the upper atmosphere which may be of most use in aerial navigation, and evolve simple practical rules for the guidance of pilots.

d Give fuller explanation of the phenomena of soaring, i.e., aeroplaning indefinitely without motive power.

e Develop equations and laws of comparison by which the behavior of large aircraft may be more accurately foretold from tests of models. Apply further the principle of dynamical similarity.

f Investigate more direct and effective methods of securing a lift or thrust in the air from the consumption of fuel.

g Complete theory of the air screw.

II ENGINE PROBLEMS REQUIRING RESEARCH

a Fuel. Possibly the most far-reaching problem is fuel. A fuel that will carry more power into an engine per unit volume will be a direct gain.

Attempts have been made to combine alcohol, gasoline, acetylene, picric acid, ether, and other hydrocarbons with the above object in view. Questionable results have followed. There has been an increase of power, but nothing so far commercially or practically useful.

This question must be studied with the greatest of care and from a truly research standpoint.

b Solid Fuel. Solid fuels that can be converted into liquid in small quantities just prior to use, are desirable for military aviation. In case of accident from shot or shock, leakage of liquid fuel is a danger. Solid fuel could be carried in quantity with less danger.

c Engine Cooling. The problem of radiation is important. If some substance could be found that would circulate through the cooling system, at higher temperatures than water, it is probable that greater engine efficiencies would result. Oils, salt waters and other materials have been tried with indifferent success.

d Liquid-Fuel Pipes. Tubing that will resist vibration (causing rupture) is desired. An oil- and gasoline-proof rubber tubing is reported as used in Europe. This development is highly important, not only for tubing, but for containers in which to carry liquid fuel. Some sort of fabric-and-rubber tank that would really resist the action of gasoline, would be of highest benefit.

A difficulty lies in the fact that the tanks are large (say 20 to 100 gal. capacity). The structural problems would be serious. The tanks now used are large and of metal. Vibration causes much difficulty and leakage.

e Metal Coating. The protecting of the metal parts of an aeroplane, especially the fittings and cables, is a serious problem. A material is desired that would really prevent dangerous corrosion. Nickel plating over copper is very good, but will not suffice. Rust strikes through very rapidly. Baked enamel is the best coating. It is impossible to apply in many cases.

f Sound. The question of eliminating the noises involved in the operation of aircraft is one of importance. The peculiar note of the propeller of a Zeppelin can be heard for several miles, and is usually the first warning of its approach at night.

III MISCELLANEOUS

a Physiological. Study the physiological and psychological effects of low-density air at high altitudes on the performance of pilots.

b Transparent Wing Covering for Aeroplanes. A wing covering which would answer the following general requirements would be of great value to military aviation:

Weight not more than 5 oz. per sq. yd. It should present reasonably great resistance to flame. It should be reasonably proof against action of salt water, moist air, extreme dryness, and quick temperature changes. It should not stretch in any direction. Its ability to retain original form as placed on the aeroplane is very important. It should have tensile strength of at least 75 lb. per in. width in any direction. Its tendency to tear and split because of tack holes through it, or because of bullet holes, should be as small as possible.

c Development of Light Alloys for Aeroplane Construction. Pure aluminum or aluminum alloys. It is believed that a great deal can be done in this direction. So far no alloy has been developed, except possibly in Germany, which can compare with average Alaskan spruce in its "specific tenacity."

d The Structure of Gusts. It is believed that this is of sufficient importance to aviation to warrant considerable expense in its study.

Painstaking investigation of the character of eddy formations caused when wind strikes trees, hollows, cliffs, etc., and the character of disturbances created by canyons, swamps, deserts, etc., would be of great value to aviators.

This can be done not only by smoke and toy-balloon work in the vicinity of obstructions such as the above, but also by photographic work in wind channels.

A set of simple rules laying down just what the aviator may expect on one side or another of canyons, cities, trees, lakes and swamps, would be very helpful in aviation.

e Radio-Apparatus for Aircraft. The subject of radio-intercommunication between aircraft in flight, and between aircraft and the earth, requires for its solution the highest possible efficiency and reliability combined with minimum weight.

A present tendency is to entirely separate the power plant from the main engine of an aircraft. The generator body in this case has a stream-line figure, and a separate small air screw is provided. Among other methods the oscillion is being tried as the actual source of continuous electromagnetic waves.

f Bullet-Proof Gasoline Tanks. Development of a material with which to line or construct tanks to contain the gasoline in an aeroplane in which a bullet hole will quickly close, entirely or partly at least. This would enable many a flier to beat back to his own lines after having been fired upon.

g Development of a Fabric as Good as, or Better than, Irish Linen, for the covering of aeroplanes. There has not

been manufactured in this country a fabric suitable for use in covering aeroplanes.

The fabric should answer all requirements laid down under Transparent Wing Covering, and be, in addition, such as to shrink the proper amount without harm when cellulose solution is applied.

It is possible that long-fiber cotton might be developed that would answer the purpose.

We must become independent in all lines affecting our military aviation. To-day we depend entirely upon Ireland and England for our linen, and the supply is becoming very low in this country.

h Aviator's Clothing. Much is still to be done in devising non-inflammable and protective clothing for aviators. This question is intimately connected with personal armor and safety in case of fall.

i Ground-Speed Indicator. An instrument which would measure the actual speed of an aircraft over the ground would be useful in the operation of military machines.

IV PHYSICS OF THE AIR

a High Frequency. At present we have no evidence of vibrations in the air much greater than 40.000 to 60,000 cycles per sec., but there is no reason to deny the possibility of vibrations of 100,000 to 200,000 or even a million cycles per sec. in the ordinary air we breathe. If these vibrations exist, may not they have an important function to perform in nature? The reason, of course, we do not perceive them, if present, is because they are above the upper limit of the human ear, and also do not directly affect any of our other senses. Although, in general, viscosity would operate to rapidly damp out these high vibrations, yet the real nature of viscosity at extremely high frequencies is not sufficiently understood at present to be dogmatic about it. The present efforts of the master physicists in the study of the constitution of matter should, before long, make the securing of high-frequency data in air of importance.

Electromagnetic waves of these frequencies existed through all time unperceived until Hertz devised a "detector." At present the detector for high-frequency air vibrations is the manometric flame, and it would be of great importance to invent a detector for air vibrations which would indicate their presence or absence up to 500,000 or a million per sec. If we had such a detector and also means for producing such vibrations in air, it would be possible to provide a system of intercommunication, over short distances at least, based upon ultra-audible sound waves. We could, for instance, devise a noiseless foghorn as an aid to navigation.

b Elasticity. The elasticity of the air has been made to serve in a great variety of machines to perform useful work. The original dynamite gun of Zalinski utilized the elasticity of compressed air as the explosive for propelling the projectile.

The best condensers for radio-telegraphy employ air as the dielectric. Any breakdown automatically repairs itself and thus adds greatly to reliability.

The passenger automobile itself has been made possible by the development of the pneumatic tire.

c Friction. The magnitude of the friction of the air against the surface of bodies moving through it may absorb large amount of energy. The average velocity of shooting stars is 25 miles per sec., and varies from 10 to 30 miles a second. The earth's orbital velocity is about 19 miles a second. It is sometimes added and sometimes subtracted from the shooting star's velocity according to the way the body enters the atmosphere. The friction of the air at these velocities is so great as to volatilize metals.

A mass of one gram of air moving with this velocity, 25 miles per sec., has a kinetic energy of 8.0937×10^{12} ergs, which is sufficient to lift one ton of matter, 2000 lb., to a height of 298 ft. above the earth's surface. One gram is a small amount of matter to possess this potentiality. This enables us to comprehend, in part at any rate, the disastrous results of the cyclone, where houses and forests are bodily cut down as by a giant steel knife.

d Mass. A cubic foot of air at 0 deg. cent. and 76 cm. pressure weighs 0.08071 lb., according to Rayleigh. A room $18 \times 20 \times 10$ ft. contains 3600 cu. ft. The air in it, therefore, weighs 290.556 lb. In liquid or solid form this air could be removed from the room with difficulty by a strong man.

On this view it appears that we have been passing our lives on the bottom of a deep ocean of comparatively heavy fluid, and that only recently have we learned how to utilize the dynamic reaction of this fluid to construct machines for transportation freely in three dimensions in the interior of this ocean. Who among us is wise enough to foretell what these machines may yet accomplish?

Automobiles

Truck and Tractor Engines, H. L. Horning

Practically only four-cylinder engines are used in truck and tractor service. There are several important differences in the conditions under which truck and tractor engines operate. Trucks are stopped and started many times during the day and operate with considerable variation in speed. The tractor demands a steady though heavy output from the engine at approximately constant speed, the changes varying from half to full load or overload.

In the truck it is not essential to strain the dust in the carburetor or to pay particular attention to dust entering the breather, but in the tractor it is absolutely essential to see that every particle of dust is removed from the air as it enters the carburetor or breather, as carelessness in this respect results in worn rings, pistons, cylinders and bearings.

Truck engines have flywheels capable of storing an average or double energy of truck-engine flywheels in order to meet satisfactorily the sudden peak loads of service.

It should be borne in mind that a pleasure car will turn over 20,000,000 revolutions in traveling 10,000 miles; a truck engine 60,000,000 in traveling 14,000 miles, while during the period of six months a tractor engine will turn over 70,000,000 revolutions in plowing 600 acres and in doing some road and belt work.

Piston displacements of American truck engines have been found to conform to the formula

$$D = 200 + 40\ T$$

in which D is piston displacement in cubic inches and T nominal pay load in tons. An investigation of American truck engines indicates the ratio of bore to stroke as 1.3, therefore

$$D = 0.7854B^2 \times 1.3B \times N = 4.1\ B^3$$

$$B = \sqrt[3]{\frac{200 + 40\ T}{4.1}}$$

where B is bore of cylinder and N the number of cylinders, which is four.

Fig. 1 shows the characteristics of a well known truck engine. This diagram shows that at three speeds in the curve peaks there occur, first, maximum torque at 783 r.p.m.; second, maximum horsepower at 1150 r.p.m., and third, maximum economy at 1011 r.p.m.

It would be ideal if these speeds were identical and if the truck engine could operate at all times at the one best speed. This is impossible, if only because of the influence of each characteristic on the other.

The speed of the maximum torque is established by the combined influence of cylinder cooling, flame propagation, volumetric efficiency, carburetion, compression leakage, and mechanical losses. At the speed of maximum torque the influence of cylinder walls on cooling the charge is on the decline. Turbulence of the charge and flame propagation are on the increase. Volumetric efficiency is dropping, while carburetion is improving with speed.

The speed of maximum economy, which is always higher than that of maximum torque, is established by favorable car-

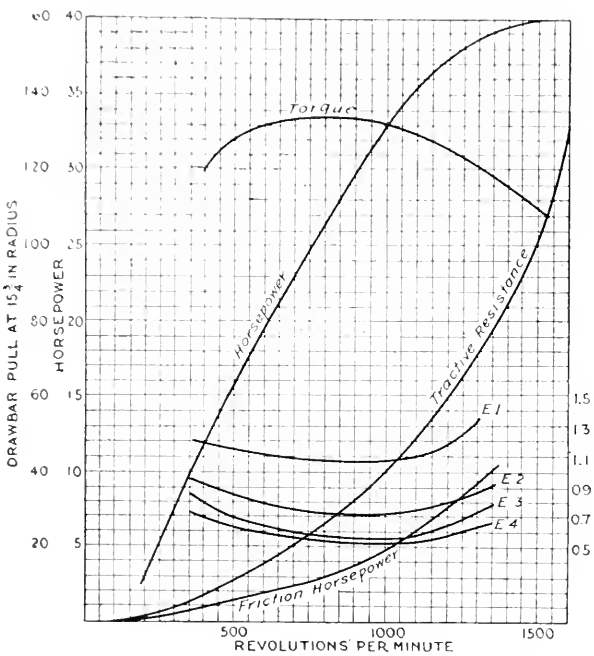

Fig. 1 Characteristics of Truck Engine

buretion, by the better atomizing of the nozzle, increased flame propagation resulting from increased turbulence, and the good, although decreasing, volumetric efficiency. The time element as affecting the radiation losses and the decrease in the unfavorable influence of water-jacket temperature on economy and torque, seem to combine for favorable theromodynamic conditions at the speed of maximum economy. Of all the influences affecting economy, carburetor setting has the greatest actual effects. Of all the influences favoring torque, engine design has the most effect.

The speed of maximum horsepower is increased favorably by violent turbulence, low cylinder-wall-cooling losses, and by the declining volumetric efficiency and rapidly rising friction losses.

From this the author proceeds to presentation and discussion of truck- and tractor-engine specifications. An interesting passage is that referring to the water pumps and engine cooling, which latter the writer calls the greatest problem in tractor engines. Little reliable information is available as to water circulation or radiator capacity. A well-known company is making capacity tests of different radiators and fan designs for tractor service and these will soon be available. A rough rule for water-pump capacity is

$$G = \frac{BHP}{V}$$

in which G represents gal. per min. water-pump discharge through outlet to water jacket, and V is a variable dependent on engine and radiator design. For an efficient design it is 1.5, and for a poor design, 3.5.

The efficient lubrication of truck and tractor engines is second in difficulty only to that of racing engines. Successful lubrication of heavy-duty engines requires that oil make a film between wearing surfaces and act as a conveyor of heat. As the duty of an engine increases, it is hard to tell which is the more important function. The writer throughly believes in the great benefit derived from a large quantity of oil carrying the heat through the lower part of the cylinders and crank case into the lower pan, where the design should be such as to permit dissipation of this collected heat. An abundant screen area for thoroughly straining the oil is of great importance in heavy-duty work.

The writer discusses in detail the application of tractor engines and gives formulae for the tractor drawbar pull and for the speed of tractor engines in terms of the bore. (*S. A. E. Bulletin*, vol. 11, no. 1, p. 1, October 1916, 19 pp., 3 figs., *et.A*)

Methods of Comparing Automobile Performance, Walter T. Fishleigh

The writer discusses the factors of automobile performance, and among other things states that automobile performance varies directly as S, the speed range in high gear in m.p.h., A, the average acceleration of car in ft. per sec. per sec. over the complete range of its operating speeds, E, the average fuel economy over the complete range of its operating speeds in miles per gal., and C, the riding comfort factor, which must be determined by each individual. The item C must be left to personal judgment, but the other items are each susceptible of scientific determination and measurement. The combination of these three factors $S\ A\ E$ constitutes what the author calls the "automobile performance factor," which affords a valuable comparison for cars.

The writer discusses the determination of the performance factors as well as performance or ability formulæ other than the one proposed by him, such as the old ability formula, Pr/WD, and the vehicle coefficients of Myers, Roebuck, and Thomas. The Thomas Sigma formula among other things includes the average gasoline consumption in m.p.h., while the Brush ability formula represents excess drawbar pull per lb. of weight, and in this way gives an accurate measure of hill-climbing ability and the approximate measure of acceleration.

In the discussion which followed, Cornelius T. Myers expressed the belief that the factor of speed range is open to argument because as the speed is decreased the difficulty in obtaining satisfactory operation is increased. If the speed range is an essential factor which should be considered in direct proportion, the ratio of the high to low speeds should certainly be used.

C. C. Hinkley cited in a modified form the formula brought out by the Franklin Company. Divide the product of displacement in cu. in. and the gear ratio by the weight times the wheel diameter. If it is desired to introduce other factors, set a standard test of from 5 to 50 m.p.h.

$$\text{Ability} = \frac{\text{Displacement} \times \text{Gear Ratio}}{\text{Weight} \times WD \times t}$$

The quicker the acceleration from 5 to 50 m.p.h., the greater the ability.

E. Planche suggests that in order to make the automobile performance formula more precise, it be given the form $S\ A\ E/L$, where L is the lowest speed that can be maintained on high gear with the car running smoothly. (*S. A. E. Bulletin,* vol. 11, no. 2, p. 123, November 1916, 22 pp., 5 figs. *p*)

RETARDATION, John Younger, Mem.Am.Soc.M.E.

Paper read before the Pennsylvania Section of the Society of Automobile Engineers, November 22, 1916. The author is chief engineer of the Truck Department of the Pierce-Arrow Motor Car Corporation, Buffalo, N. Y.

During the past two or three years emphasis has been laid on the accelerative ability of cars, while the significance of retardation has not gripped the people's imagination, even though it is of more vital importance. The automobile death rate increases in inverse proportion to the efficiency of the retardation curve.

Retardation can be studied under two heads: *A*, relative to the road, and *B*, relative to the forces acting on the car. The primary object of the former is to slow down and actually stop the car. The object of the second is to maintain the vehicle at a steady, safe speed, notwithstanding the forces such as effect of gravity in hill climbing that are tending toward acceleration.

TABLE 1. STOPPING TIMES AND DISTANCES OF CARS GOING AT VARIOUS SPEEDS UNDER COMPLETE BRAKING.

	Stopping Time. Sec.	Stopping Distance. Ft.
A car going 60 m.p.h.	11	484
A car going 30 m.p.h.	$5\frac{1}{2}$	121
A car going 15 m.p.h.	$2\frac{1}{2}$	$30\frac{1}{4}$
A car going 5 m.p.h.	0.625	$4\frac{1}{2}$

Retardation relative to the road is a function of the coefficient of adhesion or friction of the tire. The writer found an adhesion of 0.6 for solid rubber tires on cement and vitrified-brick roads, and only 0.5 under similar conditions for pneumatics. The author uses the term *adhesion* for the case where the tire does not slip relatively to the road. When the tire slips, the proper term is *friction*. As the coefficient of adhesion is greater than that of friction, this partly explains why the car stops more readily when the wheels are kept moving than when they are locked.

For possible retardation, the author gives a formula of retarding force, namely, $0.5\ W/2$, or a maximum retardation of about 8 ft. per sec. per sec. With this latter he obtains the data given in Table 1 for stopping time and stopping distance of cars going at various speeds. This table is of importance, as it disperses the claims frequently made of brakes being able to stop cars going at rates from 30 to 50 m.p.h. within the car's own length or thereabouts.

The discomfort produced by too rapid a deceleration is next discussed. Experience has shown that a deceleration of 6 ft. per sec. per sec. is about all that can be borne in comfort by passengers.

It is thus seen that for an average vehicle there is little to gain in putting brakes on more than the two rear wheels.

The question of continuous braking, such as on a long hill, is different, since here the problem is not inertia effect but absorption of energy, and hence reduction of heat. If a 5-ton truck, gross weight 20,000 lb., is going down a hill of 10 per cent grade a half-mile long, it has a gravitational component down hill of approximately 2000 lb. Assuming a road resistance of 50 lb. per 2000 lb., or 500 lb. gross, we have a net force tending to accelerate the truck down hill of 1500 lb. If a safe speed of 10 m.p.h. is maintained, the time of descent is 3 min. The energy absorbed by the brakes is 1500×2640 ft-lb. or 40 hp. or 1700 B.t.u. per mile, which means enough heat generated in 3 min. to raise the temperature of the mass from 60 deg. fahr. to 900 deg. fahr.

It is therefore the writer's impression that as the country roads get opened up more and trucks are used in outlying districts, the demand will arise for a third brake for hilly districts which will enable the vehicle to coast down a long incline at a predetermined safe speed with no wear and tear on the engine or undue heat of the brakes. (*The Automobile,* vol. 35, no. 22, p. 929, November 30, 1916, 3 pp. *tA*)

THE RESISTANCE OF IRON AND STEEL TO COMPLETE REVERSALS OF STRESS, W. C. Popplewell

A brief discussion of previous work in testing steel by alternating stresses, and description of three sets of experiments carried out by the writer himself.

An attempt was made to predict the limited stress for an unlimited number of direct reversals by the Bauschinger method of slow reversals, with two separate bars. Each of these bars was first subjected to ten slow reversals under specified stress, and then extensometer readings were taken in tension and compression to show the position of the elastic limits. The bars were than subjected to the same treatment, under successively higher loads in steps of $\frac{1}{4}$ ton.

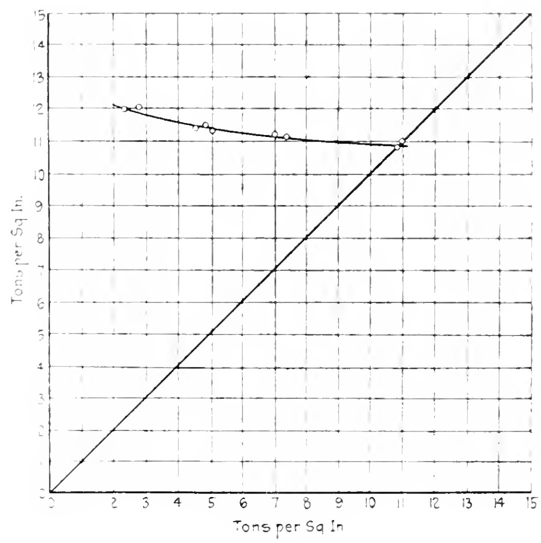

FIG. 2 DETERMINATION OF ELASTIC LIMIT BY SLOW REVERSALS

The results of these two sets are shown plotted in Fig. 2, from which it is seen that the line drawn to include the points of both bars cuts the 45 deg. line at the point just below 11 tons per sq. in., suggesting a limiting stress of not more than 11, or, say, $10\frac{3}{4}$ tons per sq. in., which corresponds to a range of $21\frac{1}{2}$ tons per sq. in.

The second set of experiments comprised the *rotating-beam tests*. In these the bar under test was $\frac{3}{4}$ in. in diameter and ran in ball bearings 20 in. apart from center to center. The

force causing the bending moment was applied at two points toward the middle of the bar, 5 in. apart. This force was derived from a hanging rod through a pair of ball bearings attached to the ends of the cross bar at the top of the rod carrying the load. The result was a constant bending moment in the 5-in. length in the middle, of magnitude $\frac{1}{2}W \times 7\frac{1}{2}$ in-lb., where W is the load. Any point in the middle 5 in. was subjected alternately to a tensile and a compressive stress each time the bar turned completely around, the value of these stresses being easy to calculate from the magnitude of the load. The speed of reversals was 350 per minute, which is lower than that employed in many cases of high-speed machinery in existence. It has been, however, proved before that for any speeds likely to be met with in running machinery the limiting stresses are independent of the speed.

The results of the rotating-beam experiments are shown in Fig. 3, where the applied stresses are plotted vertically and the number of reversals necessary to cause fracture, horizontally, the result being a curve which tends to become tangential to a line drawn through a stress, which is taken as the value for an unlimited number of reversals. In this case the limiting stress suggested by the direction of the curve appears to be somewhere about 19.6 tons per sq. in., or through a complete range of 39.2 tons per sq. in.

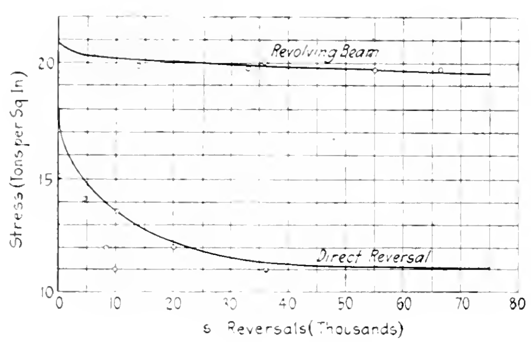

Fig. 3 Rotating-Beam Tests

For *experiments under reversals of direct stress* was used a combination of a reciprocating movement and the deflection of a flat spring. The former was derived from the movement in a milling-machine attachment, there being in this an eccentric with a throw of 3/8 in., giving a reciprocating movement to a slide block through a connecting rod 2.5 in. long.

The end of the slide block further from the eccentric has a continuation into which the end of the specimen under test is screwed, so that, as the shaft carrying the eccentric revolves, one end of the specimen is reciprocating through 3/8 in. on either side of its central position, the other end of the specimen being screwed into a holder which forms part of a clamp gripping the middle of the spring. This spring has a span of 14 in., its ends passing between supports which prevent movement in either direction.

When the machine is running and the point of attachment of the connecting rod with the sliding piece is in its mid-position, the spring is in a state of ease and there is no force applied to the specimen. But when the slide reaches its extreme position on the side further from the spring, the latter will have been deflected from its central position through 3/8 in. by a force in tension applied through the specimen. The net result is that during one revolution of the shaft the specimen is subjected to a complete cycle of stresses proceeding from a maximum in tension through zero to a maximum in compression and back again. This spring is made of 7 plates, each 0.075 in. thick and 2.25 in. wide, and it was found from experiment that a load of 110 lb. is required to deflect the spring through 3/8 in. on either side of its central position.

In order to simplify the experiment it was found convenient to vary the stress by changing the diameters of succeeding specimens, and with them the areas of their cross-sections.

The results obtained are plotted in Fig. B, where it is seen that the curve tends to become horizontal at a stress of 11 tons per sq. in.

The results obtained by the writer are tabulated in Table 2. Among other things it has been found that the actual form of the part of the rotating beam which carries the greatest stress has considerable influence on the numerical values of the results. It has been further found that, apparently, it is possible to find the stress which a given sample of steel is capable of sustaining for an unlimited number of reversals without damage, and that this can be done by "static" tests of the nature described above.

This plan has the advantage that an ordinary testing machine can be used, capable of exerting both tensile and compressive loads, and has the further merit of quickness as compared with endurance tests carried to destruction. (*The Engineering Review*, vol. 30, no. 4, p. 120, Oct. 16, 1916, 3 pp., 8 figs. *e*)

The Annealing of Carbon Steels as Affected by Various Temperatures and Magnetic Fluxes, R. B. Fehr

Data of tests carried out at the Engineering Experiment Station, Pennsylvania State College, State College, Pa., with the primary object of studying the range of temperature in which the various steel heat-treating operations should be carried out.

The writer has been unable to find in published form any series of tests that would show the variation in physical properties due to small variations in temperature throughout the critical range. As usually the temperature is varied by 50 deg. cent. intervals, it would be of interest to find the effect of small temperature variations, with the object of determining what advantages could be derived from better temperature control.

In the same series of tests an attempt has been made to determine whether there was any unusual effect on the physical properties of steel from being subjected to heat treatment and the action of magnetic flux simultaneously. It was believed that, as heat brings iron and steel into a mobile condition, magnetic flux in connection with heat might facilitate this rearrangement of the structure, and thus help to bring about a more complete transformation, with a consequent beneficial effect on the physical properties.

At temperatures above 750 deg. cent., iron and steel are practically non-magnetic, and therefore cannot be affected by magnetism; but when steel cools below this temperature and regains its magnetic properties, it may be that magnetism might have some good effect if induced in the metal during the process of cooling past the magnetic critical point. The chances are that alternating currents would give the best result on account of the constant shaking or vibration of the molecules.

Among other things, the writer made a determination of the critical point of iron, with the result that an electromagnetic method was evolved, whereby the critical point of a piece of steel under heat treatment would be determined directly and accurately. This method depends upon the loss of magnetic properties of steel at a critical temperature, and upon electromagnetic induction. The writer describes the method and apparatus in detail. Essentially, an electromagnet was placed around the heating furnace in such a way that the magnetic circuit was completed through the piece of steel undergoing heat treatment, but, instead of placing the coil about the heated part, the writer located it outside the furnace, in such a position, with respect to the magnetic field, that the sudden change of residual magnetism at the critical point would be made use of. This change of residual magnetism was indicated very sharply on a millivoltmeter by breaking the electromagnetic circuit.

In order to obtain a strong magnetic flux which would be exerted on the bars at the same time that they were undergoing heat treatment, the field of an old Manchester bipolar, series-wound dynamo was set up on end with the end yokes removed.

The two steel rods under test served to complete the magnetic circuit. The magnetic field due to a few amperes was exceedingly strong, and the flux density was considerably beyond the knee of the saturation curve for every grade of steel tested.

In the determination of the critical point the method of procedure was to break the field circuit at regular intervals during the heating and cooling processes.

The tests were run on 0.04, 0.28, and 0.835 per cent carbon steel, ¾-in. round bars.

Several tests showed quite conclusively that the electromagnetic method of obtaining the critical temperature gave practically the same result with high-carbon steel as the thermoelectric method, but that with low-carbon steels the thermoelectric method was not sufficiently sensitive, which may be due to the fact that in these steels there are really three distinct critical points, each of which is characterized by only relatively slight evolutions of heat.

The results are given in the form of tables and curves. In particular, with 0.04 per cent carbon steels, the elastic limit of the rolled bar was decreased about 6000 lb. per sq. in. by the annealing treatments, but otherwise the curves of the plotted results (Fig. 4) show practically no change in the physical properties due either to annealing temperature, or to treatment with magnetic flux, except in the case of the elongation, which shows a slight jog just above the magnetic critical point. These results are therefore entirely in accord with the

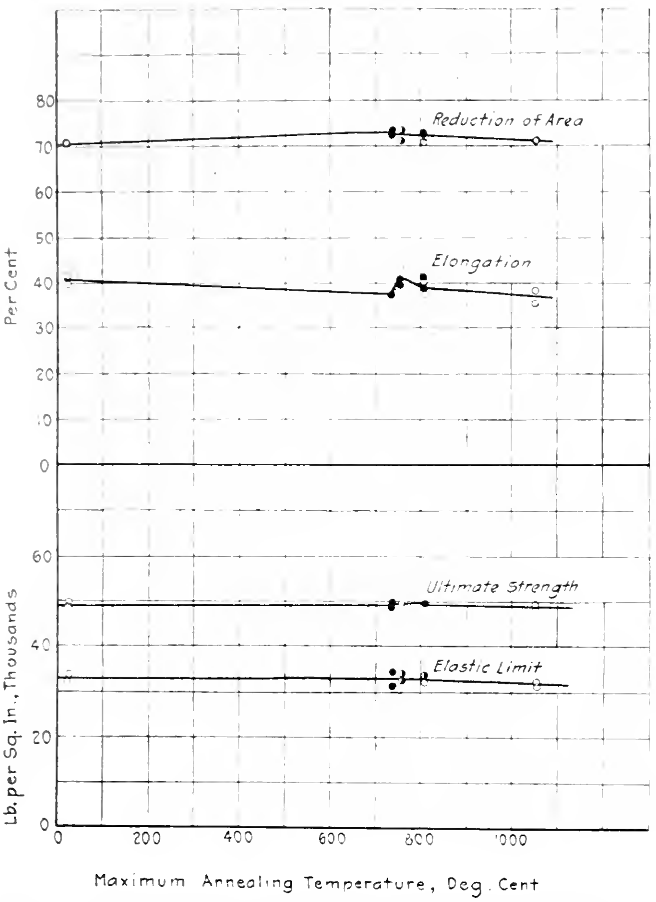

FIG. 4 VARIATION OF PHYSICAL PROPERTIES WITH ANNEALING TEMPERATURE, 0.04% CARBON STEEL

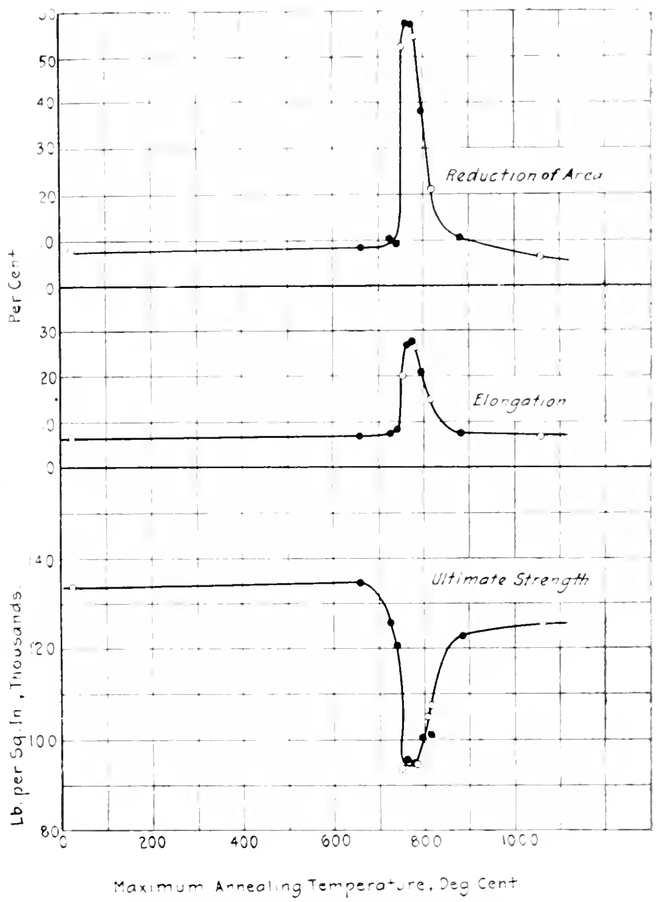

FIG. 5 VARIATION OF PHYSICAL PROPERTIES WITH ANNEALING TEMPERATURE, 0.835% CARBON STEEL

known fact that low carbon steels are very little affected by heat treatment.

The results of this series of tests with 0.28 per cent carbon steels show that the annealing temperatures around the magnetic critical point have considerable effect on the physical properties, especially the elongation and reduction of area. In raising the annealing temperature from 740 deg. cent. to 761 deg. cent. the elongation was suddenly increased 22 per cent. and the reduction of area 20 per cent, both of these properties falling off gradually to their former values at the temperature of about 880 deg. cent.

Finally, tests on 0.835 per cent carbon steels show (Fig. 5) the remarkable effects which the small variation in the annealing temperature has upon the physical properties of a high-carbon steel. Simultaneous treatment with magnetic flux did not appear to have any effect whatsoever. The author calls attention to the fact that the range of annealing temperatures recommended for this grade of steel was between 790 and 815 deg. cent., which would not have brought about maximum ductility or reduction of area, as shown by the tests.

The writer found that in all his tests the magnetic critical point indicated without exception the proper annealing temperature to give the finest grain, maximum ductility and reduction of area, and therefore the maximum shock-resisting qualities. This temperature in all cases lies within a range of 30 deg. cent. just above this critical point. It was found that, by careful temperature control, a high-carbon steel can be given the ductility of a low-carbon steel, and at the same time possess a higher elastic limit and ultimate strength than are to be found in low-carbon steels.

The experiments showed that in the annealing of carbon steels the ductility and reduction of area increase as the grain size decreases, but that the tensile strength and elastic limit decrease with decrease of grain size.

The results obtained by this investigation apply, as the author points out, only to the annealing of carbon steels. (*Abstract from advance copy of a paper to appear as Bulletin No. 18 of the Engineering Experiment Station, Pennsylvania State College*, State College, Pa. *e*).

MODERN IDEAS IN HEAT TREATMENT

Description of the methods used at the plant of the Steel Products Company, Cleveland, O., having for their purpose the elimination of variations in the quantity of heat-treated products.

The output of the Steel Products Company consists largely of automobile-motor valves, poppet valves, spring-shackle and steering-knuckle bolts and valve tappets, made of both common and alloy steel, demanding the best of heat treatment.

The uniformity of results is being secured here by maintaining a uniform quality in the gas supplied to the furnaces, which again involves the thorough mixing of scientifically predetermined proportions of gas and air. The mixture is distributed to the furnaces under a constant pressure, which is maintained by a constant-speed centrifugal fan located between the mixer and the furnaces. The gas-mixing apparatus developed by German engineers is based primarily upon the idea of mixing gas and air at the same pressure. This feature of equalizing the pressure of the gas and the air is essential if the proportions of each are to be accurately controlled, this control being accomplished by a counterbalanced gas governor into which the gas is received as it flows into the mixer from the gas meter. The governor is shown to the right in Fig. 6. The air is mixed at atmospheric pressure, with the gas entering from the gas governor. After leaving the mixer, the mixture is forced through the pipes to the different furnaces by a 15-hp. constant-speed centrifugal pump, which maintains a constant pressure regardless of the amount of the mixture being consumed.

As the mixture of gas and air in the proportions to produce perfect combustion is explosive, only part of the air necessary to insure this perfect combustion is taken in through the machine. The remainder is added to the burner itself by means of a Bunsen attachment.

The proper mixture for each installation is determined with the aid of a test Bunsen burner. These test burners operate on the principle that the height of the combustion cone is related to the pressure and proportions in which air and gas are mixed. With this system, only enough air is supplied to the burners to insure proper combustion, which results in a material economy of gas.

An interesting feature of this plant is the system of centralized control of furnaces. The gas from the pump is piped to the operator's house. Valves located in this house lead to the furnaces. Because of the fact that the gas is supplied to the furnaces through a single pipe for each furnace and because the mixture of gas and air is adjusted before it passes through the regulating valves, a pyrometer man is enabled to regulate the temperature of each furnace separately from his control board. The test burner and pressure gage located in the operator's house not only serve to indicate if the pressure and quality of the gas are being maintained as desired, but also serve to indicate the cause of trouble in case of accident to the mixer or pump. Furnace temperatures are indicated in the control house by pyrometers. (*The Iron Trade Review*, vol. 59, no. 21, p. 1047, November 23, 1916, 4 pp., 5 figs. *dp*)

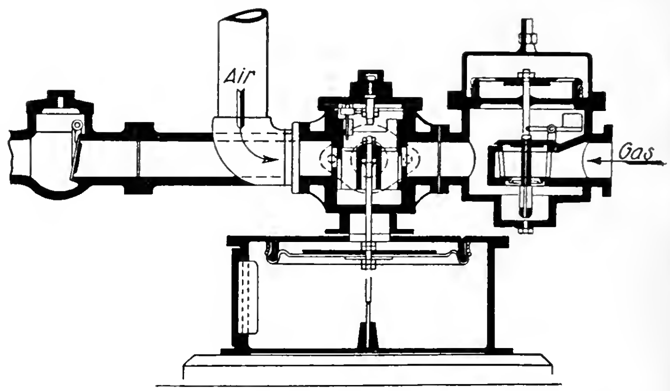

FIG. 6 COUNTERBALANCED GAS GOVERNOR FOR HEAT-TREATING FURNACES

THE TENSILE STRENGTH OF ASBESTOS ROPE WHEN EXPOSED TO FIRE, J. Bobaricoff and W. Mramornoff

As it has been suggested that asbestos ropes might prove serviceable as life lines at fires, the writers have investigated the strength of such ropes under conditions similar to those which they would have to meet if so used.

A. F. Cirkel has tested asbestos ropes having a core of other material. He states that a rope of this kind ½ in. in diameter was good for 200 lb.

The ropes tested in the present instance were three in number—two of asbestos and one of hemp. The larger of the two

asbestos ropes. No. 1 was 1 in. in diameter and was built up of 4 x 4 x 4 x 3 x 3 = 576 primary yarns. No. 2 rope, also of asbestos throughout, had 3 x 3 x 3 x 3 x 3 = 243 primary yarns, while No. 3, the hemp rope, consisted of 7 x 3 x 3 = 63 yarns. None of the ropes had a core of other material. The asbestos used was chrysotile from the Urals and had a hygroscopic water content ranging from 1.1 to 1.2 per cent at 18 deg. cent. with the air at 50 per cent humidity.

The first series of tests was made with the ropes in condition as received. As the ropes for use in fires would be liable to be wetted, it was also considered of interest to test asbestos ropes after three days' immersion in water. It was found that rope No. 1 lost 12.3 per cent of its strength and rope No. 2, 4.4 per cent.

A further series of tests was made on strands unwound from the ropes heated to different temperatures in a Heraeus electric furnace. The maximum temperatures reached were maintained for 3 hours in every case. The results are shown in Table 3, and indicate clearly that the strength diminishes

TABLE 3. TESTS OF STRENGTH OF HEATED ASBESTOS ROPE

TABLE 4. EFFECT OF REPEATED HEATING ON THE STRENGTH OF ASBESTOS ROPE

	Breaking load. kg.	Loss. per cent.
Temperature 140 deg. cent.	119	15
Temperature 210 deg. cent.	29.6	81.5

very rapidly as the temperature of each rope heated is increased. The next series of tests was made on specimens first heated and then immediately cooled down again as soon as the limit temperature was reached. It was found that the loss in strength was increased by prolonged heating.

To see the reason for this loss of strength on heating, a determination was made of the loss of weight when the asbestos was heated for three hours in the electric furnace and allowed to cool in a desiccator. It was found that the loss rapidly increases after a temperature of 550 deg. cent. is reached.

On the whole it was found that loss of strength and loss of weight for the most part ran together, but that if the maximum temperature does not exceed 299 deg., this rule fails. The rapid loss in the resistance occurs at a somewhat lower temperature than the corresponding rapid loss in weight. This is apparently due to the heat destroying the cohesiveness of the constituents somewhat sooner than it is able to expel the products of decomposition.

The large loss both in strength and weight between 200 and 350 deg. cent. is due to the burning out of the organic matter.

Tests were made on strands heated in the furnace and loaded at the same time. The temperature was raised until the strand broke. In the first series the strand was loaded with a weight of 30 kg., and broke when the temperature reached 650 deg. cent. The same strand unheated showed a resistance of 70.5 kg.; heated and cooled, 39 kg.

Some additional experiments were made on the effect of repeated heatings followed by cooling in water. A number of specimens were first raised three times to 400 deg. cent., cooled twice, and then broken. It was found that repetitions of the heating process have relatively little effect on the strength. For purposes of comparison some tests were also made on the effect of temperature on the strength of the hemp rope No. 3, with the result shown in Table 4.

On the whole the tests indicate that asbestos ropes such as tested in this case cannot be considered as suitable for use as life lines at fires. Similar ropes with steel cores would be stronger, but the asbestos would then serve merely as a heat insulator, for which purpose it is not very well adapted, as it becomes very brittle at a temperature of 600 deg. cent.

All these tests were carried out in the mechanical laboratory of the Tomsk Institute of Technology, in Siberia, Russia. (*Engineering,* vol. 102, no. 2654, p. 451, Nov. 10, 1916, 2 pp., *c*)

THE COMBUSTION AND FIREPROOFING OF WOOD: SOME MINUTE REACTIONS, James Scott

The writer discusses the process of combustion of wood on the basis of some experiments made by him on pine shavings.

He laid a thin shaving, about 1 in. long and 1/4 in. wide, upon a glass slide, with nearly half of it projecting beyond the edge. This free part was then ignited, and when it had finished burning there remained the suspended white ash, the shape of which would be easily discerned by transferring the slide carefully to the stage of the microscope. It was then observable as a fine, delicate skeleton framework of the destroyed cells.

A glowing ember of wood affords a wonderful spectacle under the microscope, where one can see the flare traveling among the cells, charring them and leaving an ashy trelliswork of disclosed walls.

In the test with the pine shaving partly under the glass slide, one can distinguish the gradation from one condition to another in the process of burning. The heat, while consuming one area, liquefies the cell contents in the vicinity and drives some of them further away in the opposite direction, thereby expanding and bursting the cells and discharging from them gases which feed the oncoming fire.

Fig. 7 shows, on a dark background, a small portion of the burned shaving, wherein all phases from intact to destroyed wood are visible.

When wood is burning and water is played upon it, the main result, according to the view of the author, depends, first, on the mineral matter contained in the water, and, second, on the mineral ash released from the already consumed substance. Hence, he believes that purposely made hard water containing, say, excess lime, would check the progress of the flames at a quicker rate than would be the case with distilled water.

When wood is burning the fundamental carbon is given off as myriads of infinitesimal specks, and if it be allowed to rise onto a glass slide it shows remarkable patterns due to a particular arrangement of the particles. In Fig. 8 is shown the filigree occasioned in a thin, gray layer of wood smoke, the carbon molecules evidently having been contained in gaseous or semi-vaporous globules, which, on meeting the solid glass, subside so that their walls produce rings and their contents central nuclei of various forms. Some of the soot is found as shining, tarry films, and the rest as a lusterless powder. (*The Railway Engineer,* vol. 37, no. 442, p. 261, November 1916, 3 pp., 3 figs. *e*)

Internal-Combustion Engineering

Carburetion at High Altitudes

Symposium of Answers of Various Carburetor Manufacturers to an Inquiry on the Above Subject

C. W. Findeisen states that if the carburetor has been carefully adjusted at lower altitudes and shipped to high altitudes, it is necessary to cut down the supply of gasoline to some extent.

G. T. Briggs, of the Wheeler & Schebler, Inc., states that in their Model L carburetor it was found necessary for high-altitude work to change the adjustment—that is, to turn on a little more gasoline at the needle and use a weaker spring. It was found that turning on more gasoline did not change the fuel combustion, owing to the rarity of the air. The Model R carburetor works well without changing the adjustment at high altitude, although a change will decrease the consumption. The experience of this company is that in order to get satisfactory results a little more gas must be supplied, also the spring must be changed in order to get more air into the carburetor through the auxiliary valve. This is due to the fact that the suction is much lower at the higher altitudes. If no change in adjustment is made, the carburetion is bad and the fuel combustion high at over 5000 ft. elevation.

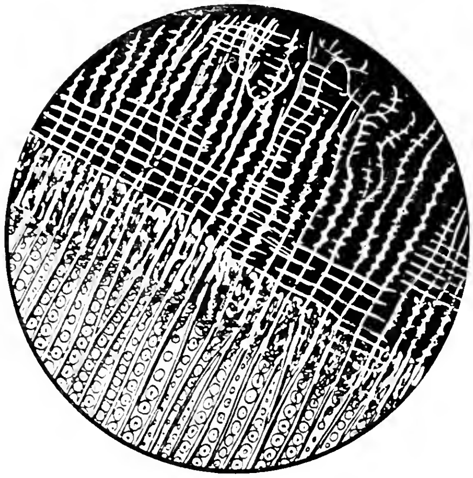

Fig. 7 Magnified View of Pine Shaving, the Upper Part of which has been Burned to an Ash, with an Intermediate Charred Zone. Diameter of Space about 1/24 in.

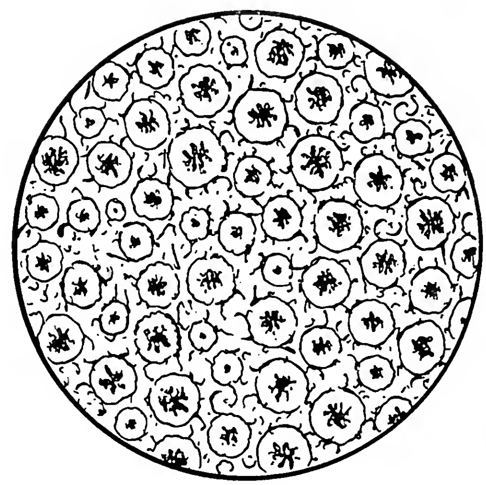

Fig. 8 Magnified View of Film of Carbon from the Burnt Pine Shaving. Actual Diameter of the Space about 1/24 in.

Arthur B. Browne, of the Malleable Iron Fittings Company, in discussing the theory of carburetion at high altitudes, calls attention to the fact that the mean effective pressure of the engine is a function of the compression pressure. An engine having 70 lb. per sq. in. compression in New York should have a mean effective pressure of about 91 lb. per sq. in.; in Butte, which is at an elevation of nearly 6000 ft., this same engine would give a mean effective pressure of only about 81 lb. per sq. in., as a result of the lowered compression only. Hence a truck engine developing 40 hp. in New York, would develop but a little over 35 hp. in Butte if supplied in both cases with the same mixture. The loss would in fact be even greater because of a slower flame propagation in the mixture at lower compression and other considerations, while the decreased negative work of compression would be a factor on the other side.

The author makes the following practical suggestions: (1) Reduce the gas in the carburetor and the adjustments at all speeds as accurately as the instrument will permit; (2) advance the spark as far as possible; in fact, until the engine gives a sharp knock, when it should be retarded until the knocking ceases; (3) remove the governor or at least set it much faster than usual.

According to F. C. Mock, of the Stromberg Motor Devices Co., the rareness of the air decreases the relative opening of weight- or spring-control air valves. This is taken care of by using larger primary openings and lighter springs. The change in mixture proportion is only a small part of the difficulty, as the heat-up of the engine makes its operation uneconomical.

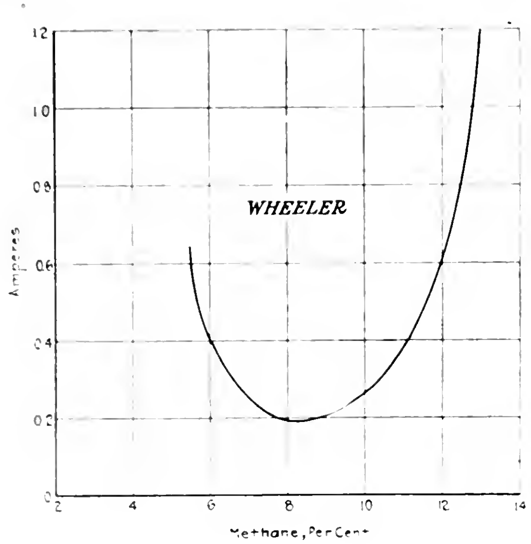
Geo. M. Holley, of Holley Bros. Co., states that his company has adjusted carburetors at Kenosha, Wis., on Rambler cars, and shipped them to Denver, Colo., which is at an altitude of 5000 ft., but could find absolutely no difference in the operation of the device.

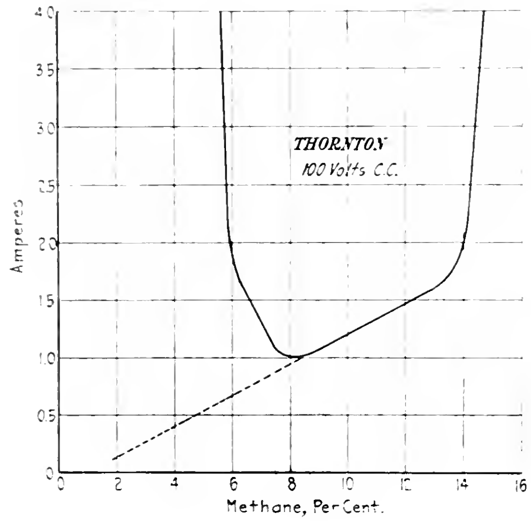
In this connection it may be of interest to compare the experiences with Diesel engines at high altitudes described in The Journal, October, 1916, p. 833. (*S. A. E. Bulletin*, vol. 11, no. 1, pt, Oct. 1916, 3 pp, *p*)

Ignition of Explosive Gas Mixtures by Electric Sparks, J. D. Morgan

The ignition of an explosive gas mixture by a spark is commonly considered to depend upon the communication of heat from the spark to the gas, but experimental investigation tends to indicate that ignition depends, at least partly, and perhaps entirely, upon some other cause than this. It does not seem likely either that temperature is the determining factor in ignition, because it is known that if the temperature is not accompanied by a sufficient quantity of heat, ignition will not occur.

Further, if it be assumed that heat alone, when accompanied by sufficient temperature, is capable of causing ignition, it would apparently be right to suppose that the mode of producing electric sparks containing sufficient heat would have no effect upon the igniting property of such sparks, which again is found not to be the case. For example, Prof.





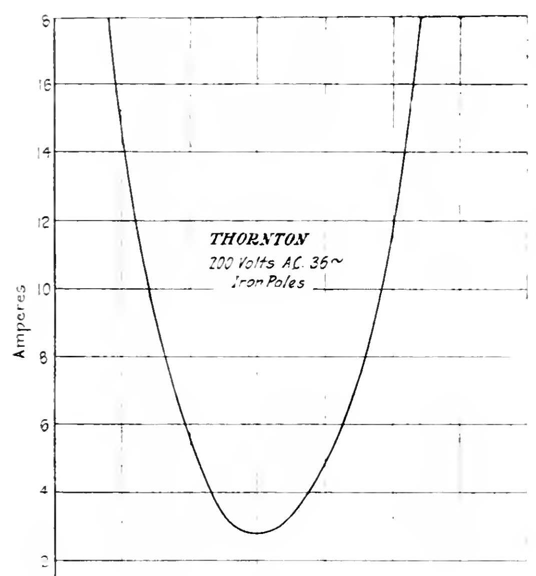


FIG. 9 (TOP) AND FIG. 10 (MIDDLE) VARIATION OF LEAST CONTINUOUS CURRENT REQUIRED TO PRODUCE A SINGLE IGNITING SPARK, WITH THE GAS MIXTURE; FIG. 11 (BOTTOM) SAME, WITH ALTERNATING CURRENT

W. M. Thornton found that a greater amount of energy is required to produce an igniting spark by an alternating current than by continuous current, and the relationship between the number of volts and amperes in the circuits immediately prior to the production of the spark differs in character in the two cases.

These and other experiments suggest ionization as the origin of ignition. Dr. H. F. Coward expresses the opinion that the ignition of an inflammable gas mixture is largely governed by two factors, namely, its thermal conductivity and the energy degraded when the discharge is passed.

In a general way it is known that gas mixtures are only combustible when the proportions lie within certain limits. Fig. 9, taken from R. V. Wheeler's Home Office Report on Battery-Bell Signalling Systems, shows how the least continuous current required to produce a single igniting spark varies with variations in the gas mixture.

From this it is seen that the most sensitive mixtures lie between 7.5 and 9 per cent of methane. The first value of this curve is to show the limits of inflammability and the general character of the current variation between these limits. This curve has been obtained on an alternating-current circuit, and Professor Thornton, who used a continuous current, obtained a curve of a different form, as shown in Fig. 10. It must be borne in mind, however, that the ordinates of these two curves are not comparable, since the least igniting current diminishes as the voltage or inductance increases.

In Fig. 10 a portion of the curve follows closely the straight line which passes very nearly through the origin. From this Professor Thornton argues that the igniting current is proportional to the number of molecules of combustible gas in unit volume of the mixture. With alternating current, Fig. 11, the character of the curve alters, the current varying as the "square of the excess of either of the combining gases on each side of the point of maximum inflammability."

The writer considers the validity of the method of determining the ability of the spark to ignite the gas, or the "incendivity" of the spark, by specifying the number of volts and amperes or the number of amperes and the inductance in the circuit prior to the formation of the spark.

With alternating current the amount of current for a given voltage is always higher than in the case of direct current, but all data show that the amounts of voltage and current or current and inductance capable of producing dangerous sparking are comparatively small. This emphasizes the necessity of adequately protecting electrical apparatus to which explosive gases are accessible, which in particular applies to the case of electric bells.

The author finds that a single spark which, when repeated slowly will not ignite the gas, will, after a more or less definite interval, produce ignition when repeated rapidly, which indicates that the element of time is a factor of importance in ignition phenomena. If, instead of a single-break device, a vibratory make-and-break device, such as the trembler of a bell, be employed, the ability of a spark to ignite a gas mixture is found to depend upon the duration of the spark as well as upon the circuit conditions.

A writer in the *Electrical Review* (vol. 77, p. 65, 1915), on the basis of the work of Professor Thornton and Dr. Wheeler, states that the igniting power of a break-flash depends on the $Li^{.354}$ of the circuit, where L is the inductance and i the circuit current.

As regards the use of the product volts times amperes, vi, as in measure of the power of the arc, the author points out that the value of vi is not necessarily the same during arcing as

when the contacts are brought together, and there is no reason for assuming them to be the same when the arc is only of momentary duration. Therefore, *m*, as it exists prior to sparking, is not a measure of the power of a hot-point spark.

The general conclusion to which the author has been led by his experiments is, that it is necessary to distinguish between the energy which produces a spark and that quality of the spark called by him "incendivity," which enables the spark to cause ignition, and that the magnitude of the one is not a measure of the other, although there may be a more or less regular relation between them when certain physical conditions are kept constant.

Ignition seems to depend on the ionization caused by the spark during the interval of sparking. The ionization may be rapidly dissipated or neutralized. If the neutralizing action predominates, there is no ignition of a gas mixture. If there is little or no neutralizing action, ignition occurs immediately. Between these two limits there are a variety of intermediate conditions which apparently account for the delay of ignition found in some of the experiments and much of the great irregularity that is often experienced in experimental work on the subject.

The rest of the paper refers to dangerous sparking of electrical apparatus for mining and of electric bell-signaling circuits. In this connection, the writer believes that the British Home Office Regulations, limiting the highest permissible voltage in bell-signaling systems to 25, does not secure safety, and the limit ought to be reduced to 6 volts. The fixing of the voltage limit in itself, however, is not sufficient to insure safety, and there should be added the condition that sparks produced in the system should not be capable of igniting a specified mixture of methane and air, which result can be easily obtained with a relay.

E. A. Watson, in a written discussion on the above paper, expressed his belief that the value of the minimum energy in the spark required to ignite a gas would be affected by the pressure, and still more certainly by the temperature, of the explosive mixture before ignition. The fact that, although one spark will not ignite a given mixture, yet a rapid succession of sparks will do so, might be due to the heating of the mixture by the energy liberated. The problem of how the horsepower given by an engine depends, other conditions remaining the same, upon the energy given by the magneto, is one which would well repay investigation. There are, however, no data available to show whether an increase in brake horsepower might be obtained by increasing the energy at the spark plug. (Some rough experiments made on a comparatively low-speed gas engine give a negative result, but these experiments were only very rough and cannot be considered as being at all conclusive, especially as the effect would be most marked at high engine speeds.) (*The Journal of the Institution of Electrical Engineers,* vol. 54, no. 254, p. 196, January 15, 1916. 13 pp., 11 figs., *et*)

INTERNAL-COMBUSTION TURBINE. A. W. H. Griepe

Description of the construction and operation of a 100-hp. internal-combustion turbine which, it is said, has made a number of runs with an efficiency estimated by a rough test at about 20 per cent.

The turbine consists of a rotor similar to that used in a reaction-type turbine, with the blades distributed in four equally spaced groups around the periphery of the wheel, each group occupying one-eighth of the circumference. On the rotor is mounted a valve band which acts as an admission and cut off valve between the explosion chamber and the fuel and air supply. The stationary element contains the explosion chamber and ring chambers for the fuel and air supply. The nozzles are mounted so that the gases flow from the inner to the outer periphery of the wheel.

The operation of the turbine is as follows: Compressed air enters the air chamber from the storage tank at from 45 to 75 lb. and gas from the fuel chamber at approximately atmospheric pressure. The compressed air flows in through specially formed passages, and in doing so acts as an injector and draws the fuel in through a small, straight nozzle in the center of each valve. By means of a special arrangement in the valve ring, the port between the fuel and the explosion chamber is closed an instant before the port is opened from the explosion chamber to the blade, and at this instant the charge is ignited and expands.

The operation of the turbine may be seen from the cycle diagram in Fig. 12. Starting at I, explosion is complete and the ring valve is just beginning to open the air valve,

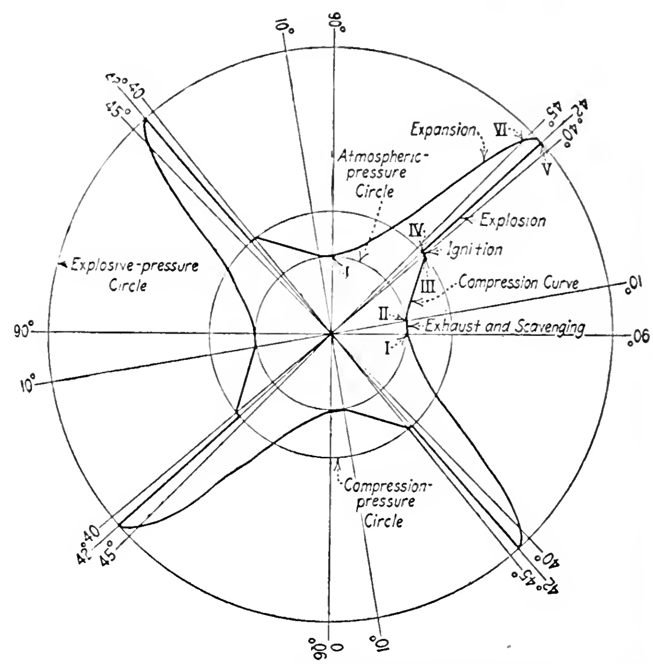

FIG. 12 CYCLE DIAGRAM OF AN INTERNAL-COMBUSTION TURBINE

with the explosion chamber still open to atmosphere. Air is admitted to the explosion chamber, blows out through the exhaust, and scavenges the explosion chamber. This continues for 10 deg. of the revolution, at which point the nozzle from the explosion chamber is closed by the inner rim of the rotor. At II, the valve band opens the fuel valve, admitting a fresh mixture into the explosion chamber, and the pressure rises, owing to the pressure of the compressed air. At III, 40 deg., the valve band closes the admission opening. When the valve band has overlapped one degree, at IV, 41 to 42 deg., ignition takes place. At this point the highest pressure, V, is obtained. From 42 to 45 deg. the nozzle is opening from the explosion chamber and expansion begins. From 45 deg., VI, to 90 deg. the nozzle is wide open and expansion takes place. At 90 deg. the cycle is complete and begins over again.

In the first installation a 3-in. by 4-in. Gardner compressor was used. The amount of air delivered was large enough for two explosion chambers, the air leakage between the tank and the explosion chamber being at that stage about 25 per cent.

Adjusting nozzles were then installed and reduced the losses to about 10 per cent. A 6-in. by 6-in. double-cylinder Curtis compressor was then installed with modified means to reduce the leakage. With the best arrangements thus far developed, the power necessary to compress the air was about 12 per cent of the whole power developed.

The combustion never gave any trouble.

The blades are made of cast iron and inserted in the rotor. The sections are cast in one piece.

No data of any tests are given, but from a statement made in another connection it appears that runs were made at speeds up to 3500 r.p.m. (*Power*, vol. 44, no. 23, p. 785, December 5, 1916, 3 pp., 14 figs., *d*)

Machine Parts

Friction Clutches. Wm. G. Gass

The writer divides all clutches into a number of distinct types, such as claw couplings, friction cones, internal-segment-and-band clutches, external-segment-and-band clutches, plate clutches, brush clutches, magnetic clutches, and automatic clutches, and discusses the distinctive features of each type separately.

As to friction materials, the author believes that while they are of advantage for brakes, there are difficulties in the way of using them for clutches. In most cases rivets have to be depended on, and these are apt to give way. The material is liable to glaze, particularly in a clutch thrown in and out many times. Where steel is employed it should not be used on cast iron unless its surface is chilled very hard. The trouble of driving surfaces is that they wear away, and this wearing is greater or less as the clutch slips or not. If there is slippage, the surface generally being dry, a small portion of matter gets embedded into whichever of the surfaces is softer and acts as a kind of plow into the other. It is not necessarily the softer of the two which gives way, but often the harder.

Clearance is the main difficulty with clutches, and the smallness of it is the cause of a considerable amount of wear when running out of gear. In all cases where the setting up is done by screws, the clearance between the driving part and the driven is relatively smaller. Attempts have been made to increase the clearance by racks to rotate the screw through a pinion, but this does not enable the necessary pressure to be put on the screw, and there is consequently a loss of efficiency. Generally speaking, clutches of all kinds wear away more quickly out of gear than when they are in gear, even where they are strong enough to easily cope with the load. Clearances are, therefore, a weak spot in almost all types of clutches, being so small that any wear which occurs in the bushes of the free part of the clutch affects its running.

Setting-up Gear. The action of setting up a clutch is the conversion of a sliding movement along the shaft carrying the clutch into a pressure between the clutch surfaces. This may be properly divided into two operations. The first, that which is in the clutch itself, and the other, that by which the power for operation is applied. The locking and concentration of power may be obtained either by a double joint or by a wedge, but in both cases a slight application is necessary to transmit the power from the stationary lever to the rotating shaft carrying the clutch. The power may be applied to the clutch either to set it in gear or to release it, i.e., to put it out of gear, the clutch being in this case kept in gear by means of springs.

The matter of *pressure on working faces* is a crucial point in the efficiency of any clutch and its power to drive. It is usually considered that if an actual pressure of 50 lb. per sq. in. can be put on the surfaces, it is as much as is desirable for good working conditions, but if for any reason a less pressure is put on than that required to transmit the power, the clutch will, if it begins to slip, grind itself away quickly and, in the spring-center type, grind away all the available spring in the metal. As to pins, in spite of all that can be done they will wear away, so that if a clutch is set up correctly a very small wear on the pins and links of the toggle will rapidly reduce the effective pressure of the faces.

The *power transmitted* is proportional to the speed of rotation, and the clutch which will transmit 10 hp. at 100 revolutions will transmit 50 hp. at 500 revolutions.

Lubrication in clutches is of the greatest importance, particularly where the clutch is running idle for a considerable part of its time. If the outside portion of the clutch is the driven part, it runs on the shaft and may have to be stationary while the shaft rotates in the clutch bushes, or, if the outside is the driver, it has to run loosely on stationary shaft. This is a source of trouble with many clutches, and the lubrication of these bushes requires the closest attention, both in design and on the part of the attendant.

In starting up any friction clutch a certain amount of rubbing takes place, and when two metal surfaces rub on one another, fine particles of metal are given off. In an enclosed chamber these cannot get away, become mixed with the lubricant, and form an excellent abrasive which does not increase the life of the part. This can be obviated by an occasional cleaning of the chamber, which, however, is not usually done.

Another peculiarity of lubrication in the case of plate clutches is that where the resistance to the idle clutch is not very great, if the oil becomes thick the plates adhere because all the air is driven out between them and the resistance may not be able to make the clutch stop. Springs between the plates have been tried to obviate this, but without great success. Excessive lubrication also reduces the driving power materially.

The speed at which the clutch is to run is an important point to consider, as well as the balance of the clutch. The clutch is rapidly affected by any want of balance if the speed reaches a point at which the want of balance becomes operative. The clutch should, however, be properly balanced for any speed. The cone having no moving parts is undoubtedly the easiest to balance and keep in balance; it has, however, certain inherent defects which stand in the way of its more extensive use. Another point which sometimes affects the use of the clutches is the overall space required.

The writer discusses further the field of application of clutches. In his opinion the *ideal friction clutch* should be a combination of a friction drive and a positive drive, i.e., a friction arrangement should be used for starting up and then a positive drive should come in operation and all driving be taken off the frictional portion. The clutch, however, should be able to be thrown out of gear with the same ease that the friction drive can give, and should have all the running parts with ample clearance when running out of gear. While this is not impossible, it is very difficult to attain, especially as the clutch should always be in perfect balance, with no projecting parts, properly lubricated, and free from complications. (Paper read before the Manchester Association of Engineers, October 28, 1916; abstract made from a reprint in the *Mechanical Engineer*, vol. 38, no. 980, p. 342, November 3, 1916, 4 pp. *dg*)

Mechanics

Recent Observations on the Critical Speed of Shafts, Prof. A. Stodola

In observing the critical angular velocity of smooth shafts, the writer has been surprised to find that the deflections at the critical speed were in nowise "infinite," but that the values always remained finite, even when the shaft was entirely free and without support at one end. This finite characteristic of values and deflection appears in a still more striking form in the interesting observations communicated to him by Brown, Boveri & Co. They submitted a photograph of a rotating shaft having a slight taper, this photograph being taken at the second critical speed of the shaft. If now the trough in which the shaft is located be filled with water, the shaft at the same speed takes an entirely different shape and the deflections, which even before were not very large, disappear practically entirely. This experiment shows that in the case of shafts immersed in a liquid, for example, propeller-screw shafts sticking out from the side of the vessel, the critical speed may be permitted without any danger of producing thereby excessive vibrations. It also indicates a possible explanation for the phenomenon referred to above, namely, that apparently the deflection of a shaft is affected by the viscosity of the medium surrounding it. One may assume that a certain amount of the fluid adheres to the shaft, revolves with it, and thereby reduces the critical velocity.

This question is entirely elucidated by the data published by Dr. O. Föppl, according to which, in the case of a heavy disk, the center of gravity of the disk, the point of "breakdown" of the shaft, and the point of intersection of the geometric axes through the center of the bearing will not rotate on a straight line as has been hitherto theoretically assumed. Such a deviation from the straight line can, however, occur only if the resisting forces are not negligibly small as compared with the centrifugal and shaft forces, which must be the case in the rotation of turbine disks either in free air or in steam. (*Neuere Beobachtungen über die kritischen Umlaufzahlen von Wellen*, Prof. Dr. A. Stodola, *Schweizerische Bauzeitung*, vol. 68, nos. 18, 19, pp. 197, 209, October 28, November 4, 1916, 5 pp., 10 figs. *etA*)

Steam Engineering

Pressure Tests of Welded Boiler-Tube Vessels, Robert Cramer

Data of tests of simply welded joints tested under hydraulic pressure.

The samples were welded either by simple butt welding or in various improved ways. Among other things dished-in heads were welded on to seamless steel tubing. Some of the samples were annealed before testing, while in others the joint was welded in the same manner as the Winslow boiler tubes are welded into their headers.

The tests, in the opinion of the author, seem to show that acetylene welds of joints of the type tested can be made as strong as the tube itself. Sections of welds have been etched with a mixture of sulphuric and hydrochloric acid for about 6 hours, and the difference in appearance between the original tube and the added material was hardly discernible.

In the test with dished-in heads welded on to a seamless steel tubing, at a pressure of about 2500 lb. one dished head bulged out, the action having the appearance of the head being of rubber. This distortion strained the weld, which tore at 3000 lb. per sq. in. It is also interesting to note that in several cases a rupture occurred, not in the weld, but near it.

Similar tests were made with electrically welded joints, with the result that they appeared to be poorer than acetylene-welded joints under pressures exceeding 3000 lb. Many of the samples discharged sufficient water through a large number of very fine holes to prevent the pressure from being carried higher than 5000 lb. per sq. in. (*Power*, vol. 44, no. 23, p. 772, December 5, 1916, 3 pp., 10 figs., *e*)

Steam Motor Vehicles, Abner Doble

General discussion on steam-driven road vehicles such as automobiles, with a description of the Doble system.

One great disadvantage of the steam car has been the insufficient mileage that was obtained from the water that could be conveniently carried. The usual car did not carry condensing apparatus which would enable it to make continuous runs of much more than 100 miles without refilling. The honeycomb radiator was not used because it was feared that the thick oil was liable to clog the extremely small passages and that the exhaust steam was liable to melt the solder. It

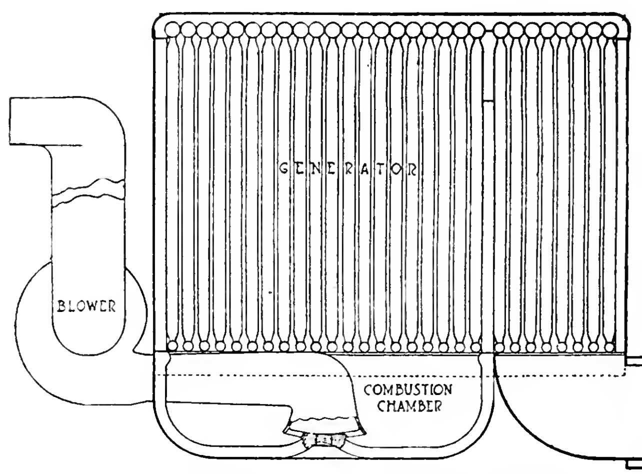

Fig. 13 Doble Steam Generator for Motor Vehicles

was also believed that oil would injure the boiler by causing violent foaming, as the successful lubrication of the steam engine required a heavy oil. The writer states that he put a honeycomb radiator on a car and operated it with a fire-tube boiler in 1913. He found that the car would run anywhere from 1000 to 1500 miles at one time on 24 gal. of water, the boiler operation being entirely unaffected by the oil pumped into it from the engine cylinder.

The selection of the type of boiler was a serious problem. The steam generator, Fig. 13, is a flash generator in theory, yet has the appearance of a water-tube boiler and has a water level in the evaporating zone. The close and regular heating surfaces give heat-transfer conditions resembling those of a fire-tube boiler, but the water flow in counter-current to the flow of the gases and with no circulatory flow is characteristic of the flash type. The water enters at the bottom of an economizer zone and flows to the top under the action of the pumps and gravity, the hottest water collecting at the top. From there the water overflows through a connecting pipe into an evaporating zone, where it is converted into steam. The water level is maintained to half way up the generator by an automatic by-pass valve so arranged that when the regulator tube is filled with steam the by-pass valve is closed

by the expansion of the tube, forcing the water from the pumps to lift the check valve. The water can then enter the generator. As the water level rises, the regulator tube is filled with water from an exhaust pipe leading from the water manifold. This water is not in circulation in the generator and therefore remains quite cool. The regulator tube then contracts and opens the by-pass valve, allowing the water to return to the tank.

The generator tubes are vertically swaged at the ends to half their diameter and welded into horizontal headers top and bottom.

An important disadvantage of steam cars in the past has been the loss of time in getting the burner started to raise steam. The writer tried to use a carburetor and spark plug with the blower driven by an electric motor to furnish the requisite air. Means were also found to use kerosene for starting, without recourse to gasoline. For this purpose conditions were established under which kerosene could be ignited by an electric spark. Thus, in the complete apparatus there is an electric motor directly connected to a multivane blower and a graduated kerosene pump. This pump draws a measured quantity of fuel from the supply tank and forces it through the atomizing nozzle, the resultant fog being ignited by a spark plug. To stop the combustion it is only necessary to break the blower-motor circuit. The starting of the fire takes about 6 min. and requires the care of the operator until it is going well. After the fire is started, steam is made quickly. The engine used is a single-expansion uniflow engine with a cut-off at 5 per cent of the stroke. The engine directly geared to the axle with a 47 to 48 ratio can produce enough torque to slip the driving wheels on dry ground. (*S. A. E. Bulletin*, vol. 11, no. 2, p. 158, November 1916. 8 pp., 3 figs. *d*)

Gas-Firing Installations for Steam Boilers, Pradel

Continuation of a serial article. The beginning of the article has not been abstracted, as the issues of the paper containing it have not yet been received by the Library, apparently because of the delays and uncertainties in the delivery of mails coming from Germany. It may also be stated in this connection that a number of technical periodicals have not been received because of the prohibition, by the German Government, of the export to the belligerent and neutral countries of certain technical and medical publications.

Among other things, the article describes safety devices used on the burners and piping in gas-fired boiler plants. Wherever gas firing is used, there is always the danger of the formation of an explosive mixture of gas and air. In particular, irregularities in gas pressure, such as excessive pressure or excessive velocity of the flow of gas, may tear away the flame and extinguish it for a short period. Then the continuation of the flow of gas into the firing chamber will gradually fill it with the mixture of gas and air, which may be subsequently ignited by contact with the hot walls and cause an explosion. Excessively low pressure in the gas piping may also lead to an explosion through the penetration by suction of air into the gas piping, and the consequent formation of an explosive mixture.

The Moll safety shut-off valve is proposed as a means to combat this danger. The Moll burner can be applied only where each firing chamber has one separate burner. Where a single firing chamber requires such a large amount of gas that several burners have to be installed, the Moll burners are arranged in such a manner that one burner, usually the middle one, acts as an igniting burner.

Such an arrangement is shown in section in Fig. 14. The main firing burner *a* has an auxiliary igniting burner *b* supplied with gas independently from the main burner installation, and so arranged that it can be operated independently of the same. The flow of gas from the main burner installation is automatically cut off until the igniting burner is cut in, and until it has, by the use of the reducing flame, entirely consumed the oxygen present in the air in the firing chamber. With this in view, the igniting burner is provided with a valve gear connected with the handwheel of the cut-off valve *d* regulating the gas admission to the main firing system. When the igniting burner is cut out, this mechanism grips the handwheel of the valve, and does not relieve it until the igniting burner has been cut in again.

Safety devices to protect against variations of pressure in the supply of gas and explosions produced thereby, are usually built into the gas piping proper. Essentially, they are regulators of pressure, limiting the pressure either outward or downward. In the first place, when the maximum pressure is exceeded, a by-pass is opened for the gas; in the sec-

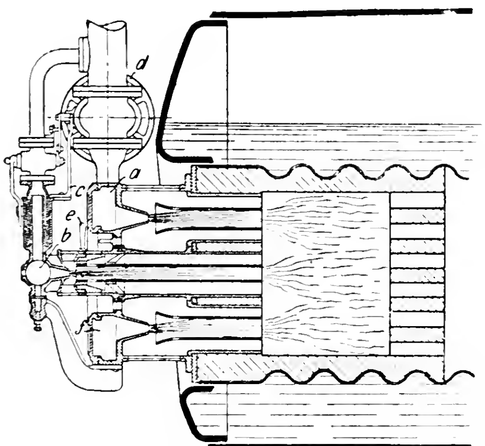

Fig. 14 Moll Burner with Pilot and Main Fires

ond place, when the pressure reaches its lowest limit, the gas supply is entirely cut off. Salau & Birkholz, for example, use a device wherein the gas-admission cocks on the burners are provided with wires attached to a minimum pressure regulator. At a certain definite minimum pressure, the regulator releases a weight, the fall of which instantly closes the cocks on all the pipes leading to a given battery of boilers.

In safety installations of this kind it is essential that the opening of the by-pass or the closing of a gas valve by the pressure regulator be of such a nature that the reverse action should not take place when the pressure reaches its normal level. The device should be so arranged that it can be reopened only by hand. This is so provided in the safety cut-off valve of the Westfalische Maschinenbau-Industrie Gustav Moll & Co., A.-G., in Neubeckum, shown in vertical section in Fig. 15. The pressure governor consists of a bell *a* immersed in a cup on the gas piping *b* filled with an inert liquid, the device being so arranged that the immersion takes place when the supply of gas falls below a certain limit. When the bell reaches its lowermost position, the pendulum *c*, suspended from the cover of the valve, moves downwards until it reaches a small groove in the bell, and thereby prevents it from rising again. The pressure of the gas then begins to act on the

liquid [illegible] at level a_0 and raises it to the position indicated by [illegible], corresponding to the highest permissible gas pressure, in such a manner that no further flow of gas can occur. The rise of the level of the liquid in the gage glass indicates to the fireman that full gas pressure is again available. In order to admit gas again to the burners, the pendulum holding the bell must be released by pulling on the handle f, or pressing down the lever g, whereupon the bell will be raised by the gas pressure far enough to permit the flow of gas through the orifices h.

The valve can be so devised that the bell may be held in place during the course of operation, that is, even when the pressure is below normal.

The article also describes the safety cut-off valve built by P. Hoss in Langenbockum, shown in section in Fig. 16. The chamber a is built in onto the gas pipes l and g, the pipes entering into the chamber by means of elbows b and b_1. Over the chamber a is located a water-filled chamber i, with a valve p on the bottom, this valve closing the short pipe k leading to the chamber a. The valve p is operated by the lever rod f,

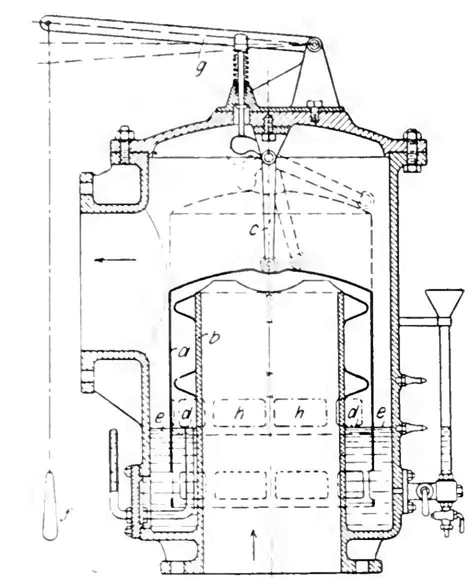

Fig. 15 Moll Automatic Safety Cut-off Valve

of which the dead weight may be equalized by the adjustable weight m in such a manner that the flow of gas is prevented from opening the valve p, which in this case is no longer supported by the flap v. In the chamber a are likewise located the floats c and c_1, running in guide cages e and e_1, these floats being arranged in such a manner that when the water level in chamber a rises they press against the openings of the elbows b and b_1. With the lever system f is connected an electric contact, in such a manner that it announces, by the ringing of the bell, the closing of the valve. The amount of water is so proportioned that the openings in the elbows b and b_1 are just covered over, but no water can penetrate into the gas piping proper. In order to start the flow of gas after some trouble has occurred, all that is necessary is to let off some water from chamber a by the cock n, and to fill anew the water chamber i, which is usually provided with a water gage and peep glass.

The Engineering Society, Its Past, Present and Future Activities, Ernest McCullough

Discussion of the objects and policies of engineering societies, with special reference to the conditions in Chicago.

The writer claims that while the engineer has become a technical man with a vocation recognized alongside the older professions of law, medicine and theology, the technical and engineering societies have not kept pace with this development. They still consider themselves as institutions organized solely for educational purposes, and the society proceedings have become encyclopedias which are consulted less frequently than are the pages of the journals maintained purely for profit.

The writer believes that the young man in the engineering society feels that he has not been paid the proper attention, and that "Engineering societies have for many years past been mutual admiration societies of successful men." The discussions at the meetings are too frequently inadequate, and real criticism is seldom developed when the author of a paper is of a commanding eminence. The young man learns something from the papers, but he feels diffident about discussing them, as he fears that his opinion would not be well received. "Get a reputation first," is the attitude of too many authors when they write a closure to a discussion.

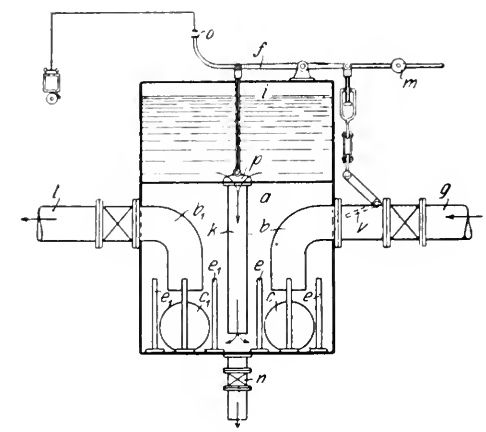

Fig. 16 Hoss Safety Cut-off Valve

The young man does not want this. He wants fellowship, companionship, and definite recognition. He is glad to attend a meeting where he knows refreshments will be served, not because of the refreshments, but because something to eat and drink signifies a lack of formality and perhaps an opportunity to mingle freely with men who have made their mark. He wants to feel that the society is more than an editorial body or an encyclopedic compilation of engineering facts.

The writer states that the young man is the central idea of the present policy of the Western Society, beginning with the new constitution of 1911, which provided for a grade known as student members.

The writer proceeds to discuss technical societies organized in Chicago by the younger generation of engineers, such as The Associated Technical Men and The American Association of Engineers, and in discussing their programs touches upon the activities of the Western Society of Engineers in connection with legislation—in particular, the licensing of engineers in the State of Illinois. As the author states, engineers were opposed to legislation to license engineers, but conditions in

the State of Illinois became so intolerable on account of the monopoly given to architects that The Western Society of Engineers obtained last year the passage of a law to license structural engineers. Further effort is being made to secure a lien law for engineers.

As regards publicity, the writer believes that the societies heretofore have concerned themselves with the publicity work of individuals. What is now a crying need is publicity work of a proper sort by the societies for the benefit of the membership, and incidentally of the technically educated men not members of any society.

It is the duty of engineering societies to break away from precedent and get back to first principles. They must become again the places where the interests of the young men are the concern of the older men. (*Journal of the Western Society of Engineers*, vol. 21, no. 8, p. 697, Oct. 1916, 12 pp. *g*)

Some Essential Features of High-Speed Engines. A. F. Milbrath

Discussion of the design of high-speed engines.

Such engines are built primarily for racing, where maximum output is the main consideration. To adapt them for stock cars certain modifications would be required to insure durability as well as to reduce the cost of manufacture. All of these modifications tend to reduce speed and mean effective pressure, so that the output is smaller as compared with that of the racing engine. The result is a compromise between high output on the one hand and durability on the other. The data presented in this paper are the result of several years' experimental work. Only the most important features are here abstracted.

In a high-speed engine a small diameter of cylinder with the long stroke is favorable, since the weight of the piston increases with some power of the diameter between the second and third, while the inertia forces on the piston vary likewise as long as the piston speed is constant. On the other hand, however, the weight of the engine will increase with the longer stroke, while the valve area will decrease with the smaller bore unless large valve pockets are used. The heat lost to the jacket water will be the less the smaller the area exposed to the gases in the cylinder. A shorter stroke has therefore its advantages. In Europe, stroke-bore ratios as high as 2 have been used successfully. From the author's experience ratios of 1.70 or 1.75 have given good results in 300-cu.-in. engines.

The volume of compression space should be about 18 to 20 per cent of the total volume, which will give compression pressures of about 90 to 110 lb. per sq. in. gage.

As to ignition, the author prefers two-point ignition with spark plugs on opposite sides, as, in his opinion, this gives more rapid combustion, more power, and reduced fuel consumption. As to valve springs, in actual practice at engine speeds of 3000 r.p.m. spring tensions of 80 lb. with valve seated have been satisfactory on $1\frac{3}{4}$-in. valves weighing, with accompanying reciprocating parts, 0.9 lb. For higher speeds greater spring tensions are necessary, which, however, involves difficulties in securing springs that will stand up for any length of time.

As to pistons for high-speed engines, the most important consideration is light weight. Aluminum-alloy pistons have the advantage of ease of manufacture, light weight, heat conductivity, and ample strength. Wristpin bearings can be formed directly in the aluminum. Thicker rings should be used, however, as thin rings are apt to wear into the aluminum, and this causes a gradual widening of the grooves.

Connecting rods should be light, but great strength is also necessary. Connecting rods, pistons and all the reciprocating parts must be balanced perfectly to insure freedom from vibration.

The writer discusses in detail the matter of crankshafts. He believes that with the shaft of liberal dimensions, sufficient mass is secured to absorb any vibrations set up by the light pistons and rods. No further balance weights are necessary, especially if the ratio of connecting-rod length to stroke is 2 or slightly greater. (*S. A. E. Bulletin*, vol. 11, no. 2, p. 115, November 1916, 8 pp., 1 fig. *g*)

Specification and Tests of the Transparency of Paper and Tracing Cloth

The Bureau of Standards, Department of Commerce, has just published a Circular under the above title (Circular No. 63). It describes a method of quantitatively specifying transparency for practical purposes, states the form of the specification and gives a description of the apparatus used to make measurements.

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general; *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society. The Editor will be pleased to receive inquiries for further information in connection with articles reported in the Survey.

A gasoline-driven two-furrow plow used in England weighs about 2300 lb. and develops about 11 h.p., requiring about 2 gal. of gasoline per acre plowed.

According to *The Engineer* (London), silver alloyed with 2 per cent of palladium forms a good substitute for platinum in contact-point and spark devices. The alloy which gives the greatest resistance to spark erosion is 60 per cent palladium and 40 per cent silver. Palladium raises the melting point and lowers the thermal conductivity.

In an interesting publication entitled "Personal Reminiscences of James Mapes Dodge," Charles Piez, Mem.Am.Soc. M.E., tells of the struggles, early failures and final great successes of one of the most commanding figures in American invention and engineering, and shows the genial, charming personality of Past-President Dodge, who did much to shape our present-day industrial ideals.

Professor W. F. Durand, on behalf of the National Advisory Committee for Aeronautics, is planning during the coming year to install at Leland Stanford Junior University, California, an aerodynamic laboratory for experimental investigation of problems in which the committee is concerned, and with special reference to the investigation of aerial propellers. He will undertake during the coming year in this laboratory an experimental investigation of such propellers, covering some fifty different forms of models, and with a view to the establishment of reliable design constants and characteristics for the use of naval and military designers and as a general aid to commercial designers in the development of this feature of the aeroplane.

Fixed Charges and Labor Cost Curves for Diesel Engines. Practical Engineer, vol. 20, no. 22, November 15, 1916.

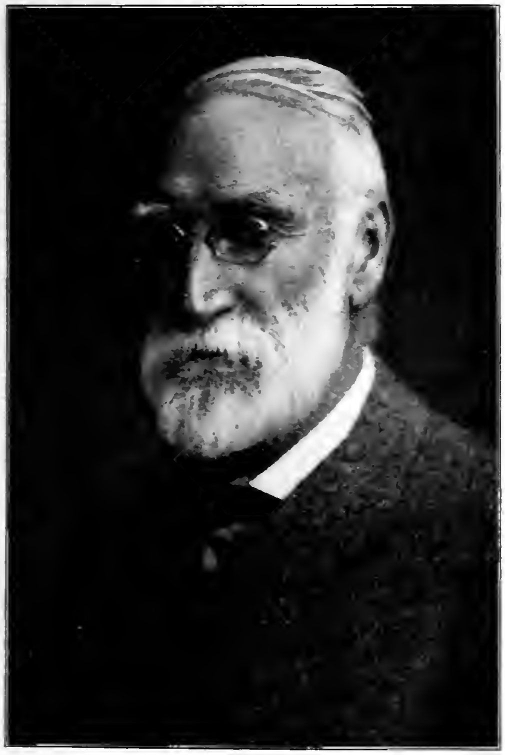
LIBRARY NOTES

From the Library of the United Engineering Society, Engineering Societies Building, New York. Includes Accessions to the Libraries of the Four Founder Societies

Dr. Douglas's Gift

Plans for the expansion of the library of The United Engineering Society are being made which will render the library unique, not only in the collection of technical books and periodicals, but also in the service it will be prepared to render to the members of any branch of the engineering profession.

These plans have been made possible by the initial gift of $100,000 from Dr. James Douglas, as the beginning of an endowment fund which it is hoped will reach $1,000,000. One



Dr. James Douglas

of the initial steps in these plans is to place on the library shelves every engineering periodical published in the world, no matter in what language, and the same broad policy will be followed in the acquisition of reference books.

Dr. Douglas's gift has suggested large possibilities, and with the consolidation of the library of the American Society of Civil Engineers with that of the three original Founder Societies, the ultimate should be a library of universal service to the engineering profession.

Am. Soc. M. E. Accessions

The John Bogart Letters. 1776-1782. *New Brunswick, N. J., 1914.* Gift of President of Rutgers College.

Chicago, Board of Supervising Engineers, Chicago Traction. Annual Report 7th, 1914. *Chicago, 1916.* Gift of Bion J. Arnold.

Heavy Timber Mill Construction Buildings, C. E. Paul. Ed. 2. *Chicago, 1916.* Gift of National Lumber Manufacturers' Association.

How to Build Up Furnace Efficiency. A hand book of fuel economy. Ed. 7, by Jos. W. Hays. n. p. 1914. Gift of G. L. Simonds & Co.

How You May Save Money in Operating Your Steam Boilers. Ed. 3. Revised by E. L. Webster. Gift of A.S.M.E.

Institution of Civil Engineers. Minutes of Proceedings. Vol. CXCIX. *London, 1915.*

Mechanical Equipment of Buildings, Louis Allen Harding and Arthur Cutts Willard. *New York, John Wiley & Sons, 1916.* Gift of Louis Allen Harding.

Messerschmitt Process for the Reproduction of Hydrogen, H. L. Barnitz. Reprinted from Metallurgical and Chemical Engineering, vol. 15, no. 8, 1916. Gift of author.

Mosquito Control in Panama. The Eradication of Malaria and Yellow Fever in Cuba and Panama, J. A. Le Prince and A. J. Orenstein. *New York, G. P. Putnam's Sons, 1916.* Price $2.50. Gift of publishers.

The joint authors were associated with General Gorgas in Cuba and Panama as chief and assistant chief sanitary inspectors. This book gives a detailed account of the conditions found, the measures adopted for mosquito extermination, and the results obtained. No engineer doing or planning work in the tropics should miss reading this work. The extermination of the mosquito made possible the completion of this gigantic engineering feat. W. P. C.

New York City Department of Bridges. Report, 1914-1915. *New York, 1915.* Gift of A.S.M.E.

New York State Conservation Commission. Annual Report 5th. 1915. *Albany, 1916.* Gift of Conservation Commission.

Pennsylvania Water Supply Commission. Annual Report. 1915. *Harrisburg, 1916.* Gift of A.S.M.E.

Queensland Harbours and Rivers. Report from the Engineer for year ended June 30, 1916. Gift of Queensland Engineer for Harbours and Rivers.

Relatif a une nouvelle determination des Valeurs des Puissances dans les Essais d'Helices. Fascicule. (A encarter dans l'ouvrage Nouvelles Recherches sur la Resistance de l'air et l'Aviation. 1914). Gift of G. Eiffel.

Tractive Resistances to a Motor Delivery Wagon on Different Roads and at Different Speeds, A. E. Kennelly and O. R. Schurig. Bulletin no. 10, Massachusetts Institute of Technology, Electrical Engineering Dept.

United States Government Publications Pertaining to Pulp and Paper, H. E. Surface. Reprinted from Paper, October 4, 1916. Gift of author.

Washington Academy of Sciences. McGee Memorial meeting, December 5, 1913. *Baltimore, 1916.* Gift of Washington Academy of Sciences.

Worm Gearing, Hugh Kerr Thomas. Second edition. *New York, McGraw-Hill Book Company, 1916.* Gift of author.

An important use for worm gearing is rapidly developing in connection with the reduction of steam turbines for marine propulsion. Other uses are for automobile gears and gears for driving line shafting from electric motors. The mere fact that a second edition is demanded so soon as in three years shows the great interest in this branch of applied mechanics. The author has added to this edition appendices devoted to efficiency, reversibility, and an alternative method of calculating stresses. W. P. C.

PERSONALS

In these columns are inserted items concerning members of the Society and their professional activities. Members are always interested in the doings of their fellow-members, and the Society welcomes notes from members and concerning members for insertion in this section. All communications of personal notes should be addressed to the Secretary and items should be received by January 16 in order to appear in the February issue

CHANGES OF POSITION

Manning E. Rupp, for a number of years with the Panama Canal, has accepted a position as superintendent with the Curtis Pneumatic Machinery Company, St. Louis, Mo.

H. O. C. Isenberg has been made chief engineer of the Scripps-Booth Company of Detroit. He was formerly associated with the Ferro Machinery and Foundry Company of Cleveland, O.

Kenneth A. Meserole, formerly in the engineering department of the American Beet Sugar Company, Oxnard, Cal., has become associated with the Stearns-Roger Manufacturing Company, Denver, Colo.

W. M. Imbrie, Jr. recently resigned as superintendent of the Chattanooga Chemical Company to become engineer in charge of construction for the Atlantic Pulp and Paper Company, Savannah, Ga.

Clarence W. Huntington, vice-president and general manager of the Minneapolis and St. Louis R.R., has resigned to accept the chairmanship of the directorate of the Virginian Railway, with office in New York City.

Arthur V. Farr, for the past three years advertising manager of the S.K.F. Ball Bearing Company, Hartford, Conn., has resigned to accept the position of sales manager of the Hess Steel Corporation, Baltimore, Md.

Philip Jones, until recently associated with the Pinal Dome Oil and Refining Companies, Santa Maria, Cal., in the capacity of consulting engineer, has assumed the duties of general superintendent of the Mid Co. Gasoline Company, Tulsa, Okla.

H. H. Lauer has resigned his position as head of the Bureau of Prices of the Midvale Steel Company, Philadelphia, Pa., to accept the position of chief engineer of construction of the Atlas Portland Cement Company, Northampton, Pa.

Charles F. Carpenter has severed his connections with the Fire-Proof Furniture and Construction Company, Miamisburg, O., and has become affiliated with The Recording and Computing Machines Company, Dayton, O., in the capacity of manager of works.

Arthur K. Howell has resigned as sales representative of the Worthington Pump and Machinery Corporation, Memphis, Tenn., and has become associated with A. A. Bonsack, formerly St. Louis manager of the Ingersoll Rand Company. Messrs. Howell and Bonsack plan to carry on a general machinery sales business.

ANNOUNCEMENTS

E. G. Spilsbury has returned from a professional visit to Cuba.

John R. Freeman, Past-President, Am.Soc.M.E., has been elected president of the Providence (R. I.) Gas Company.

The colleges of electrical engineering and civil engineering of the University of Kentucky, Lexington, Ky., have been consolidated, with E. Paul Anderson as dean.

Henry L. Doherty was one of the speakers at the reception to President Wilson in New York when the flood lighting illumination was turned on the Statue of Liberty, December 3.

Clarence E. Kinne of the Bagley and Sewall Company, Watertown, N. Y., has started on a several months' trip through China and Japan for engineering exploitation work, especially in relation to paper mills.

George H. Shepard, until recently connected with the Gould Storage Battery Company, Depew, N. Y., in the capacity of factory superintendent, has taken up consulting practice in efficiency work, with offices in Buffalo, N. Y.

Cornelius Vanderbilt, who has been divisional inspector of the New York National Guard with the rank of major, has been commissioned colonel of the 22d New York Engineers' Regiment, one battalion of which is still on the Mexican border.

APPOINTMENTS

Robert R. Jones, assistant mechanical engineer of the Firestone Tire and Rubber Company, Akron, O., has been appointed chief engineer of the company.

William M. Bastable, manager of the pump department of Fairbanks, Morse and Company, New York, has been appointed manager of the Baltimore branch of the company.

Albert H. Israel has been serving as assistant chief inspector of ordnance for the E. W. Bliss Company, since his return from South Bethlehem as resident inspector.

John Hunter, chief engineer of steam plants for the Union Electric Light and Power Company, St. Louis, Mo., has been chosen to succeed the late A. C. Einstein, as a member of the company's board of directors.

Martin Nixon-Miller, recently assistant engineer, contracting department of McClintic-Marshall Construction Company, in charge of the building operations of their new $1,000,000 bridge shop at Pottstown, Pa., has been appointed by the U. S. Government to take charge of the eight new factory building operations and to install the machinery after the completion of the buildings, at the Frankford Arsenal, Philadelphia, Pa.

AUTHORS OF PAPERS, ETC.

Halbert P. Gillette is the author of a Handbook of Rock Excavation Methods and Costs.

A. W. H. Griepe is the author of Internal-Combustion Turbine, which appears in the December 5 number of *Power*.

George L. Fowler is the author of a book on Anatomy of a Steel Hopper-Bottom Coal Car.

Clinton H. Scovell is the author of a book entitled Cost Accounting and Burden Application.

S. S. Wyer is the author of a book on The Reasonableness and Legal Right of the Minimum Charge in Public Services.

Robert Cramer has contributed an article entitled Pressure Tests of Welded Boiler-Tube Vessels to the December 5 issue of *Power*.

A. A. Potter and W. A. Buck have contributed an article on Four-Cylinder Best Tractor Engine to the December 7 issue of *The Automobile*.

Arthur J. Wood has contributed an article entitled The Kiesel Train Resistance Formulas to the December issue of the *Railway Mechanical Engineer*.

Frederick W. Salmon has contirbuted a brief article on Safe Loads on Rope Slings to the December 21 issue of *Engineering News*.

William Knight has contributed an article on Safe and Noiseless Operation of Cut Gears to the December 14 issue of the *American Machinist*.

Walter V. Turner gave an amusing and instructive address on the subject of Freak Patents before the Railway Club of Pittsburgh, December 18.

Reginald Trautschold contributed an article on Bucket Loaders for Manufactories to the December, 1916, number of *The Engineering Magazine*.

Arthur M. Greene, Jr., vice-president Am.Soc.M.E., is the author of a book on the Elements of Refrigeration: A Text-Book for Students, Engineers and Warehousemen.

W. Trinks is the author of an article on Air Delivery Factors of Blowing Engines which is published in the December number of *The Blast Furnace and Steel Plant*.

Charles P. Steinmetz is the author of an article on Scientific Research in Relation to the Industries, which appears in the December issue of the *Journal of The Franklin Institute*.

Edward C. Poultney is the author of an article on Modern British Goods Locomotives which is published in the December number of the *Railway Mechanical Engineer*.

John E. Starr presented a paper on Accidents in Refrigerating Plants at the December 4 to 6 convention of the American Society of Refrigerating Engineers, held in New York.

R. H. Rice and Sanford A. Moss presented a paper, illustrated by lantern slides, on Blast-Furnace and Steel-Mill Power Plants at the December 12 meeting of the Engineers' Society of Western Pennsylvania.

An abstract of the paper on Specifications for Concrete which was read before the American Society for Testing Materials by Cloyd M. Chapman, appears in the December 7 issue of *The Canadian Engineer*.

H. V. Haight is the author of Special Lathes for 8-In. Shells, which appears in the December 7 number of the *American Machinist*.

Frederick H. Wagner is the author of a book on Coal and Coke, published by the McGraw-Hill Book Company, Inc.

"To the West, When Wind, Tide and Weather Serve, There is Sufficient Water to Let Out the Fleet . . . Over This Lower Channel, Aswing from Wire Cables from Two Towers, Hangs the Trap's Iron Gate. The Towers Rise from a Populace Friendly to Every Nation in the World but Its Own . . . and Fond of Explosives."—*Sea Power.*

THE DEVELOPMENT OF OUR FLEET AND NAVAL STATIONS

By W. L. CATHCART, PHILADELPHIA, PA.

Member of the Society

My subject, "The Development of Our Fleet and Naval Stations," is so broad that only a rapid review of its salient points will be possible to me.

I need scarcely say that this whole question of naval strength is one of impelling interest to engineers. The European conflict has shown in many striking ways that war by land and sea is now very largely but a matter of applied science, of physics and chemistry, and chiefly of engineering in all its branches.

Years ago, Theodore Roosevelt said, in an expression which has become classic, that the naval officer of our time is fundamentally a "Fighting Engineer." This description is wholly accurate with regard to the structures and mechanisms of naval war—its huge hulls and giant turbines, its colossal guns, its dynamos, wireless, torpedoes, and air craft. The naval officer has added functions as a strategist and tactician, but it is clear that the engineer is a mighty factor in the sea power of our time.

WHY WE NEED A GREAT NAVY

Why does the United States need a great navy? In the first place, our country is the richest, and, owing to its vast extent of coast line, the most vulnerable of all the great Powers. And, second, like a modern Atlas, it staggers—diplomatically and militarily—under the weight of some national policies which, while just, are as world-irritating and war-breeding as any that history has known. These policies are: The Monroe Doctrine, The Neutralization of the Panama Canal, The Maintenance of the Rights of Neutrals, The Exclusion of Asiatic Races, and The "Open Door" in China.

The Monroe Doctrine extends our "political suzerainty over two continents, comprising a fourth of the habitable earth and one-half of its unexploited wealth." Excluding Canada and the United States, this vital and yet war-inviting policy covers twenty republics, having a total area of nine million square miles, a population of eighty millions, and a foreign trade of nearly three billion dollars. And all this is to be guarded from European seizure by the force behind a doctrine which is not international law, but simply a bluff declaration by the United States that Europe shall not enter in!

This doctrine has been a sleeping danger to this Republic for nearly a century now. Its slumber has been due chiefly to the lack of means for the swift transfer of fleets and armies across the Atlantic, and the extreme delicacy of the balance of power in Europe. The progress of steam navigation has swept the first of these away, and, as for the second, who dare predict political conditions in Europe when this war closes?

Now, take the Panama Canal. By international law, it is a part of the territory of the United States, and it is also, as a military and commercial highway, one of the world's greatest prizes. So, we must defend it. Further, by the provisions of the Hay-Pauncefote Treaty of 1901, we agreed that "the canal shall be free and open to the vessels of commerce and of war of all nations"—that is, we guaranteed its neutralization. Either of these obligations necessitates a powerful, fully sup-

Address (abridged) delivered at the Annual Meeting of The American Society of Mechanical Engineers, December 8, 1916.

PARTIAL STRATEGIC CHART, NORTH ATLANTIC OCEAN

ported fleet, and neutralization presents as well most complex and dangerous problems for the future.

We have glanced at the possible effects of but two of our national policies, and they alone hold menace enough for the future. Trans-oceanic attack can be met primarily only by a fleet. Do you wonder, then, that naval strategists foresee a time when—not in aggression, but in national defense—the mighty thunder of American guns will roll out in mid-Atlantic or on the sun-lit Caribbean, along the coasts of Europe or at the threshold of the Far East?

The surest way to delay the coming of that time is to have behind the parleys of our diplomacy a naval force stronger than those of our possible foes. All history shows that diplomacy, when backed by guns enough, can keep the peace, but notes without powder behind them are futile.

STRATEGIC SITUATION, EASTERN COAST

The elements of naval strength are: First, the fleet—its ships and men; and, second, its shore stations—navy yards at home and naval bases in our island possessions—which dock, repair, and supply the ships, and from which the fleet may strike. Manifestly, the location of these stations with regard to our possible battlegrounds of the future is of primary importance. Let us glance briefly at the strategic situation of our eastern and western coasts in this respect, as shown by charts whose use is permitted through the courtesy of Rear Admiral Knight, President of the Naval War College, and Captain J. S. McKean, Assistant to the Chief of Operations.

When invasion by a European Power is threatened, our Navy Department will know only that the enemy has set sail from some port across the Atlantic. His specific course and objective—on our coast or in the Caribbean—will be unknown. Our fleet, if strong enough, would take the offensive-defensive, and attack the enemy a thousand miles or more at sea. To locate him, our admiral would send out a long line of scouts to scour the seas in a great arc from Cape Sable in Nova Scotia to Trinidad at the lower entrance of the Caribbean Sea.

There would be four principal points of departure for this enemy fleet: from the Orkneys, the northern base of the British Grand Fleet; from the mouth of the English Channel; from the Straits of Gibraltar; or from some point on the African coast, as Agadir.

On these four lines of approach to our coast the distances range between 2800 and 4200 sea miles. To Culebra—which, if we do not acquire St. Thomas, will be our challenging Caribbean outpost—these lines are from 3200 to 3900 miles long. In the present state of naval science, these relatively great distances make successful invasion impossible, if the enemy fleet must conduct *continuous operations* on our coast *from its home bases*, or even from these eastern Atlantic islands.

There are two main reasons for this. In the first place, a naval force, steaming far from its bases, must be followed by a train of supply vessels, which train becomes huge when that force is large. And, second, fleets cannot invade. So the enemy fleet must be followed by troop transports.

And, further, unless the enemy had previously gained command of the sea, these helpless fleets of transports and supply ships of his must be guarded always while en route throughout the whole period of his operations, and by a stronger force than we could bring against them.

From these considerations, several things are clear: First—disregarding the Caribbean for the time—any enemy but Great Britain must, for successful invasion, first *seize a naval base on our coast*, from which to conduct succeeding operations. To seize that base, he must first *defeat decisively* our fleet—either destroying it, blockading it, or forcing it to withdraw to a distance. Then, and then only, when the enemy has *won command of the sea, will his convoys* of troops and supplies *be safe*.

Naval bases suitable for hostile operations are fairly numerous on our coast. For example, Delaware Bay, Narragansett Bay, Provincetown, Mass., and several others, in their present defenseless state, could be seized with ease if our fleet were first defeated.

As to our naval stations on this coast, they all lie within an air-line distance of 500 miles, although our Atlantic and Gulf coast lines are more than 3000 miles long.

If an enemy should gain possession of these 500 miles of coast, our dreadnaughts would be homeless, unless the fleet could flee to the Bay of Panama, since the yards at Charleston, Pensacola, and New Orleans are equipped for small craft only. As to these conditions, Rear Admiral Edwards says:

"There is not a dry dock owned by the Government or by anyone else on the South Atlantic and Gulf coasts which will take any of our super-dreadnaughts. There is not a single stationary or floating crane on these coasts which will remove from or install in a battleship either a modern turret gun, a Scotch marine boiler, or an assembled low-pressure turbine of the kind now fitted in our large naval colliers, tankers, and battleships."

These conditions give our strategists just cause for concern in their bearing on our undefended line of communications, 875 miles long, from Cape Hatteras to Key West, and on the distance, one-half greater, from Culebra to Norfolk.

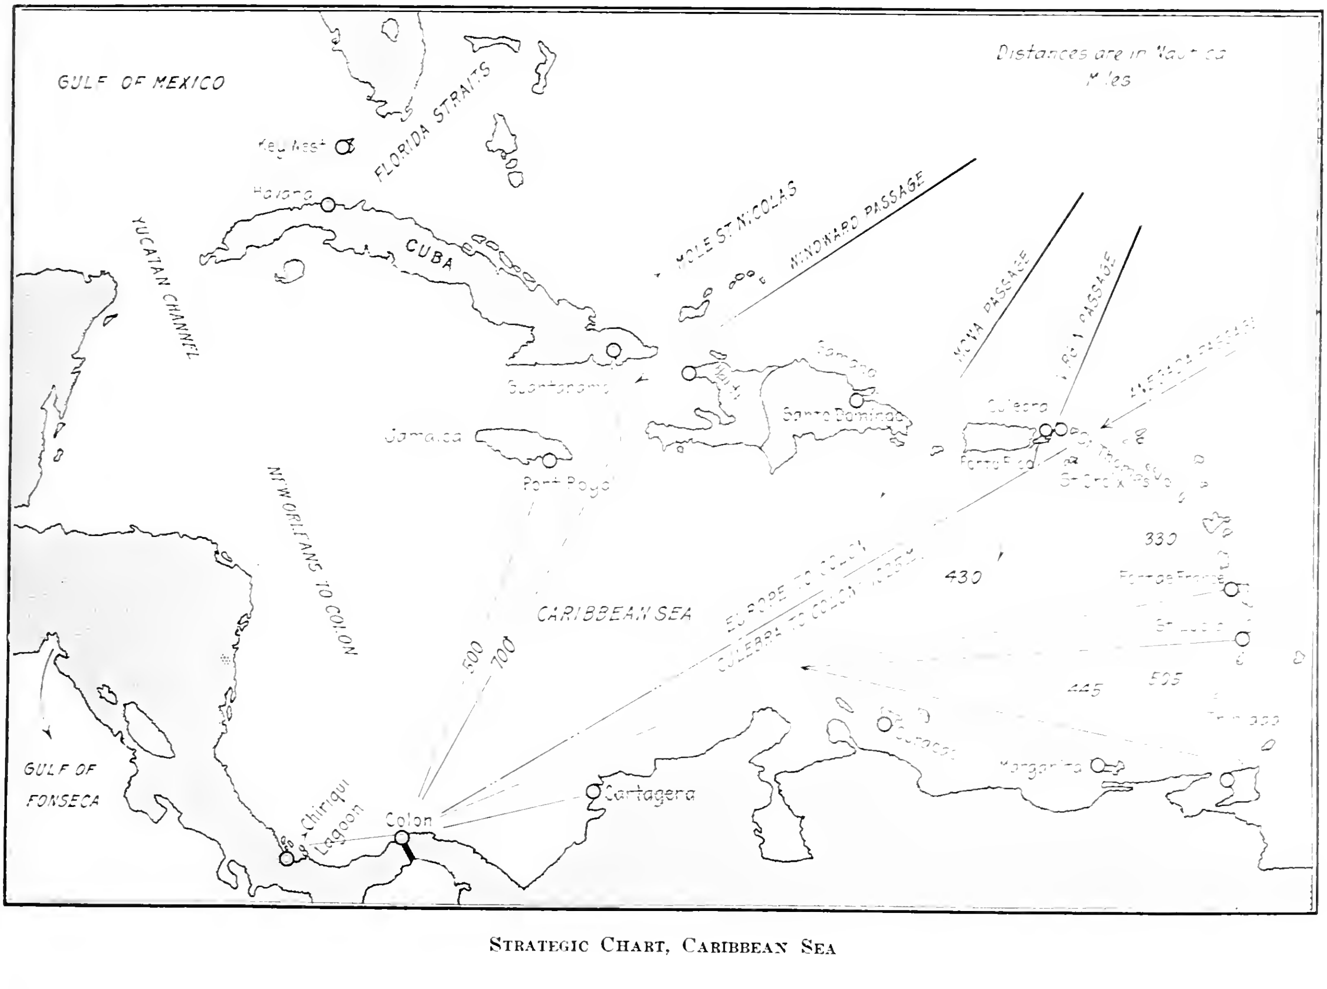
STRATEGIC SITUATION, CARIBBEAN SEA

The Caribbean Sea is—as Admiral Mahan once wrote of it—"preëminently the domain of sea power." For its size, it has more strategic positions than any other important expanse of sea on the globe. For the United States, its mastery in war is almost vital, since that mastery is the bulwark of our defense of the Monroe Doctrine and the Panama Canal.

No invasion of the United States is possible until our fleet has first been put out of the reckoning. If, then, the enemy must thus eliminate our fleet, it seems probable that he would endeavor to force action where our naval strength is most vulnerable—that is, off Culebra, where our ships would be more than 1200 miles from their home bases.

Again, *for continuous operations*, the enemy must have a naval base of his own on or near our territory, and the seizure of a small island would be far easier than that of a base on our coast.

Finally, if thus established at some point like St. Thomas or Culebra, with our fleet negligible for the time, the enemy could raid our South Atlantic and Gulf coasts at will; could flank all our routes to the Caribbean, and when—with full command of the sea—his convoys of troops had come he could invade the Canal Zone, 1040 miles from St. Thomas. Possession of the Canal would give him not only a powerful lever in bringing pressure on our Government, but would enable



Strategic Chart, Caribbean Sea

him to block the retreat of our defeated fleet to Gatun Lake or the Bay of Panama, and to prevent the coming of reinforcements from the Pacific.

Glance now at the geography of the sea. On its northern border lie Porto Rico, which we own; Haiti and Santo Domingo, which are under our virtual protectorate, and Cuba, whose independence we have guaranteed. Doubtless, every port in these islands would be open to our use in time of war.

There are five entrances to the sea along this northern border – the Yucatan Channel via the Florida Straits from the Atlantic, and the Windward, Mona, Virgin, and Anegada Passages. Dominating the Florida Straits stands Havana like a new-world Gibraltar. Near the southeastern end of Cuba lies our base, Guantanamo, which, with Mole St. Nicolas in Haiti, commands the Windward Passage. Similarly, Samana Bay in Santo Domingo controls the Mona Passage, Culebra and St. Thomas the Virgin Passage, and the latter and St. Croix the Anegada Passage, which is the main route from Europe to the Canal.

Jamaica, with its naval base, Port Royal, seemingly dominates all by its central location. But, while Jamaica has thus a commanding strategic position, it is lacking in strength against attack and in its resources for supplies and refitting. Hence, for military support and supplies, it would be dependent in war on its lines of communication with other British colonial and home ports, and from those ports it is both distant and isolated. Further, our base at Guantanamo flanks its communications with all of these ports.

Now as to our two naval bases, Guantanamo and Culebra: Guantanamo is but 700 miles from the Canal, and, as it flanks all routes to Colon except that from Jamaica, its location centrally is almost as good. Further, it has surpassing advantages in the fact that it is on a large island, which has not only great native resources, but also direct railway communication with manufacturing centers in the United States except for the short sea link between Key West and Havana. Hence, supplies can reach Guantanamo by interior land lines immune from attack by sea if the Florida Straits be guarded effectively.

As compared with Guantanamo, Culebra is about 600 miles farther to the eastward, and hence it has a far better command of the eastern entrances to the sea, flanking all routes through them by short runs of 350 to 500 miles. Again, it is but a few miles from Porto Rico, which is in itself difficult of defense. Further, as a little island, it could be fortified and garrisoned at proportionately low expense. And finally, as a salient, it flanks the lines of approach to our coast.

All of these advantages, and more, hold for St. Thomas, just across the Virgin Passage from Culebra. It also is a small island, it is still farther eastward, has a better command of the Anegada Passage, and its harbor can be strongly defended by fortifications in the high hills surrounding it. The best argument for its acquisition by the United States is, however, the negative: Suppose the unthinkable—that we should let St. Thomas pass into the hands of a strong military power unfriendly to us. Then our base at Culebra would be confronted by a rival fortress on the further shore of that narrow Virgin Passage. These conditions would be as if Gibraltar faced an equally formidable and alien "Rock," with but the Straits between.

And *the menace of that fortress would stretch far beyond the Caribbean* to our trade routes to South America, and even to our coast. For within a radius of 1000 to 1400 miles from it lie New Orleans, Key West, Charleston, Norfolk, and New York—a distance through which raiding battle cruisers or even a dreadnaught fleet could steam and fight, with ample fuel remaining for their return, if necessary, to St. Thomas.

We find, then, that the destiny of nations has given the United States full opportunity for holding the strategic mastery of the Caribbean Sea through its present and prospective tenure of predominating positions there. But strategic dominance on the sea means nothing if the sites on which it depends are not fully equipped, fortified, and garrisoned and an adequate fleet based there, since a more powerful enemy would simply wrest them from us. So these neglected West Indian bases of ours give cause for grave concern. *With them, some day, the fate of this Republic may rest.*

STRATEGIC SITUATION, NORTH PACIFIC

Let us close our strategic review with a brief consideration of our western coast and our outlying possessions in the North Pacific Ocean, where remarkable conditions exist.

In the first place, the United States owns on the shores from Panama to Kiska in the Aleutian Islands every important strategic position except three—the Galapagos Islands, Magdelena Bay in Mexico, and Esquimault, the fortified port of British Columbia. Thus, strategically—if these be developed—our power over these shores is predominating for two-thirds the width of that great ocean.

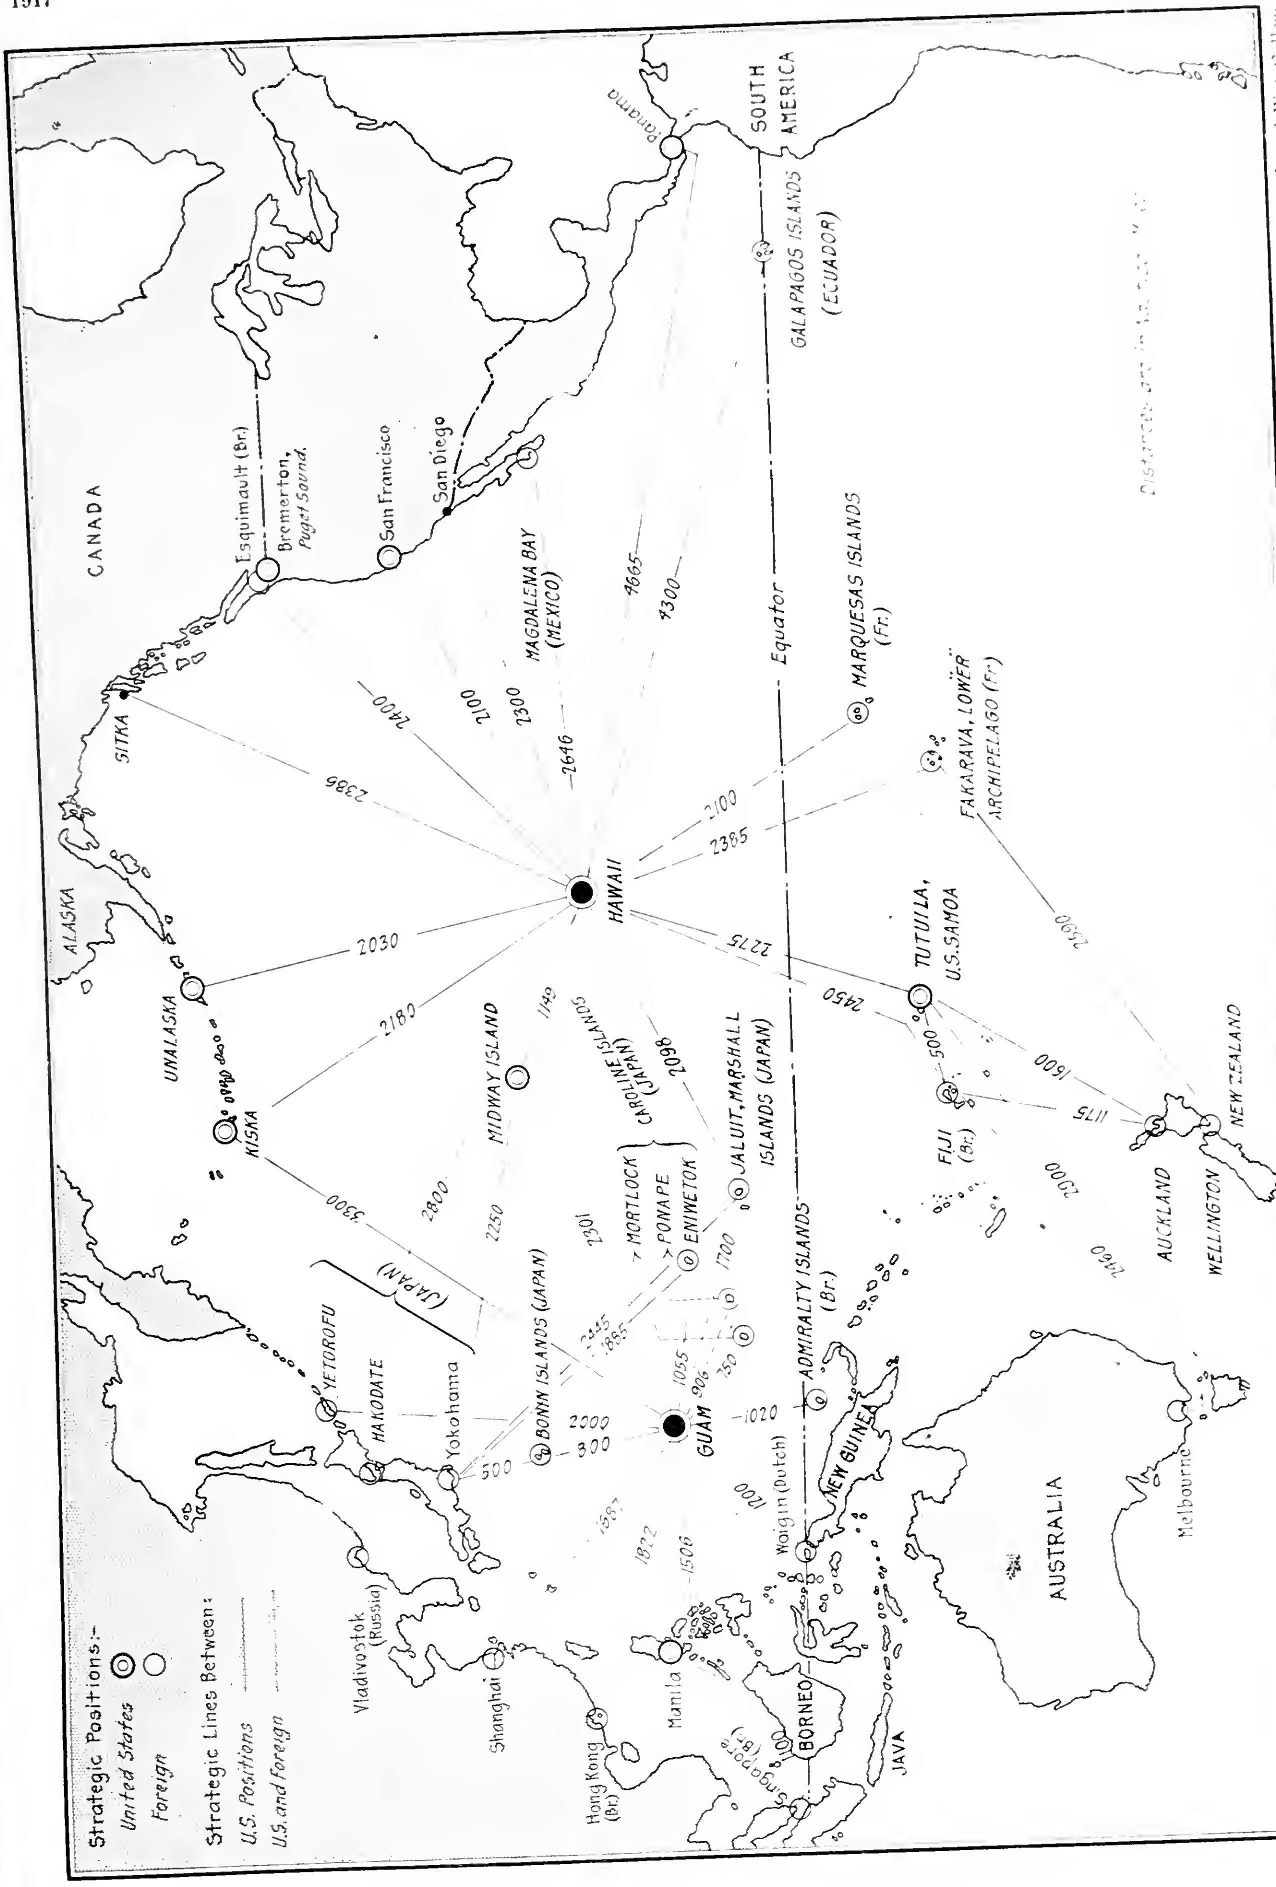
Further, spanning the Pacific like the piers of a colossal bridge from Panama lie our islands of the Hawaiian Group, and our other island, Guam, in the Ladrones, which is *the key to the military control of this northern ocean.* Then 1150 miles west of Hawaii is Midway, useless to us except as a future coaling station. And finally, 2300 miles southward, is Tutuila in American Samoa, one of the noblest harbors in the South Seas.

Steaming at 12 knots an hour from Panama, it would take a fleet 12 days to reach San Francisco, 16 days to Honolulu, 28 to Guam, and 33 to Manila. So no fleet stationed on our western coast in war could protect the Philippines and our interests in the "Open Door" in China. Hence, *for their defense and that of Alaska*—which is virtually an overseas possession 2000 miles from San Francisco—*we must rely on our island bases, Guam and Hawaii.*

Hawaii is the center of communications—*the strategic focus*—of the eastern half of the North Pacific Ocean. This means that a fleet based there can strike with equal ease, in offense or defense, at all points on the great arc of coast line from Kiska to Panama. *Hawaii thus dominates the whole strategic front formed by the shores of the eastern half of the North Pacific Ocean.*

Similarly, the strategic lines of the western Pacific all intersect near our possession, *Guam, which is thus the strategic focus of that half of the ocean—and hence a menace in war to every important position there,* from Japan's northernmost one at Yetorofu and that of Russia at Vladivostok, down the Chinese coast to Singapore in the Straits Settlements. Well within the circle of Guam's protective area lie the Philippines, indefensible of themselves, whose single stronghold is the little island, Corregidor, in Manila Bay. And also, well within its reach, stands that—now closing—"Open Door" in China. Guam is small—about seven by twenty-nine miles—has a harbor which, by dredging and building a breakwater, would shelter a fair-sized fleet, and is readily capable of defense by fortifications and mines.

Finally, a noteworthy fact as to our chain of bases bridging the North Pacific, is that the strategic line from Panama through Hawaii to Guam cuts the similar British line from



PARTIAL STRATEGIC CHART, PACIFIC OCEAN

Courtesy of U. S. Naval War College

Esquimault to Australia and New Zealand. In view of this and of the focal relations of Guam and Hawaii to that northern ocean, *the strategical predominance of the United States in these waters is—in a geographical sense, at least—unquestionable.*

Guam and Hawaii, if made ocean fortresses, would be our Malta and Gibraltar against aggression by any enemy sailing from the Far East—from Vladivostok, Yokohama, or Singapore. If in war we had strong fleets based there, no enemy from Asiatic waters would dare to pass Guam without masking or reducing it, and destroying or dispersing its fleet. And, later, he would have a similar victory to win off Hawaii before the Pacific coast would meet the shock of war. And yet, like Guantanamo and Culebra, Guam lies neglected and undeveloped there, at the very threshold of the Far East—an easy prey for any foreign nation which would dare war with us to take it. And, too, the fortification and equipment of Hawaii proceed but slowly.

As to the very striking relation of these ocean outposts to Pacific coast defense, Captain McKean, formerly of the Naval War College and now Assistant to the Chief of Operations, says:

"With Guam converted into a Pacific Gibraltar, Honolulu . . . . becomes a secondary base, and can be less strongly held against attack from the West. . . . In effect, their (Guam and Honolulu) fortifications would be an expanded and intelligently elaborated coast defense, which, combined with an adequate fleet to bind them together, would keep the enemy from ever approaching our coast."

THE NEEDS OF OUR NAVAL STATIONS

In the upbuilding and maintenance of the Navy, we shall need all the navy yards we have—and more. As a whole, these yards lack much, not only in the dredging of their channels of approach, but in modern equipment for building and repair, both as to hulls and machinery. The need of dry docks and of channels to these yards, which would be deep enough for our largest vessels at all stages of the tide, is an amazing instance of naval unpreparedness. We have been building, and are to build, giant dreadnaughts, which, at present, can be docked at only four widely separated navy yards—New York, Norfolk, Puget Sound and Hawaii. The possible consequences, after but one great naval battle, are appalling. I have pointed out the imperative need of repair facilities on our southern Atlantic coast for war vessels of the largest size. At present, Charleston seems to be the only suitable location there. Admiral Benson, Chief of Operations—in recommending a navy yard of the first-class on this southern coast—says, if "there should be any naval engagements south of Hatteras, it would be of vital importance to be able to use all the facilities that the Charleston yard offers"—and that yard is now but a very minor affair.

As to the naval bases for the defense of our outlying possessions and as frontier outposts for our coasts, the admirable locations which we now have are as yet but "the substance of things hoped for," and fatally lacking in much.

Admiral Knight, President of the Naval War College, says: "It is my opinion that the completed bases at Guam and Culebra, including the defenses * * * would cost in the neighborhood of $15,000,000—in other words, about the price of a battleship." Shall we hazard the safety of our fleet and imperil our national defense to save an amount equal to the cost of but one dreadnaught?

Every important naval station on our coast and island possessions should have its Flying Base and be equipped also with its "Mother Ship," carrying from ten to twenty aeroplanes, all fitted with wireless. These flying scouts could report the location and formation of an enemy fleet some days in advance of its appearance off the coast.

U. S. S. Oklahoma, the Latest Addition to the Battleship Fleet

HOW LARGE SHOULD OUR NAVY BE?

Not for aggression, but to keep the peace, and to exert fitly what Mahan called "the silent force of sea power," the United States needs a great Navy. How big should that Navy be?

Several conditions affect the answer. First, our unequaled and ill-defended wealth, inviting spoliation. Second, our immense territory, which—from Eastport, Maine, to Manila—stretches more than half around the world. Third, the factor of distance with regard to that territory—which factor has no parallel in Europe. England, for example, is today waging the greatest naval war of all history at but 400 miles from her own shores, while, with us, the distances to the Caribbean Sea, to the Panama Canal, to Alaska and the Philippines, are from three to twenty times greater. Fourth, the fact that "the United States Navy is really a 'Disunited States' navy," since, like Russia, with her Baltic and Black Sea littorals, we have two widely separated coasts, linked, in our case, by a canal which may fail us in a crisis—either by slides or by treacherous or direct attack with high explosives on its locks.

It would take 60 days for our fleet to steam from the Caribbean Sea around South America to Panama. The Austro-Prussian War of 1866 was won at Sadowa in nineteen days after its beginning. The Franco-Prussian War of 1870 ended at Sedan in fifty-one days after its declaration. The British Fleet—the very keystone of Allied success in the existing war—was started instantly on its fateful run of but 400 miles by the telegraphic order, "Go!" By sixty days' delay in sudden war we might lose the lands of an empire—Alaska, Hawaii, Guam, and Samoa—in the Pacific Ocean.

Hence, from every viewpoint—of strategy and of common sense—the conclusion is inevitable that we should keep permanently in each ocean a battle fleet strong enough to defeat decisively any probable enemy there.

This in itself means a great Navy, but the General Board states that we should go farther still, that "the Navy of the United States should ultimately be equal to the most powerful maintained by any other nation of the world."

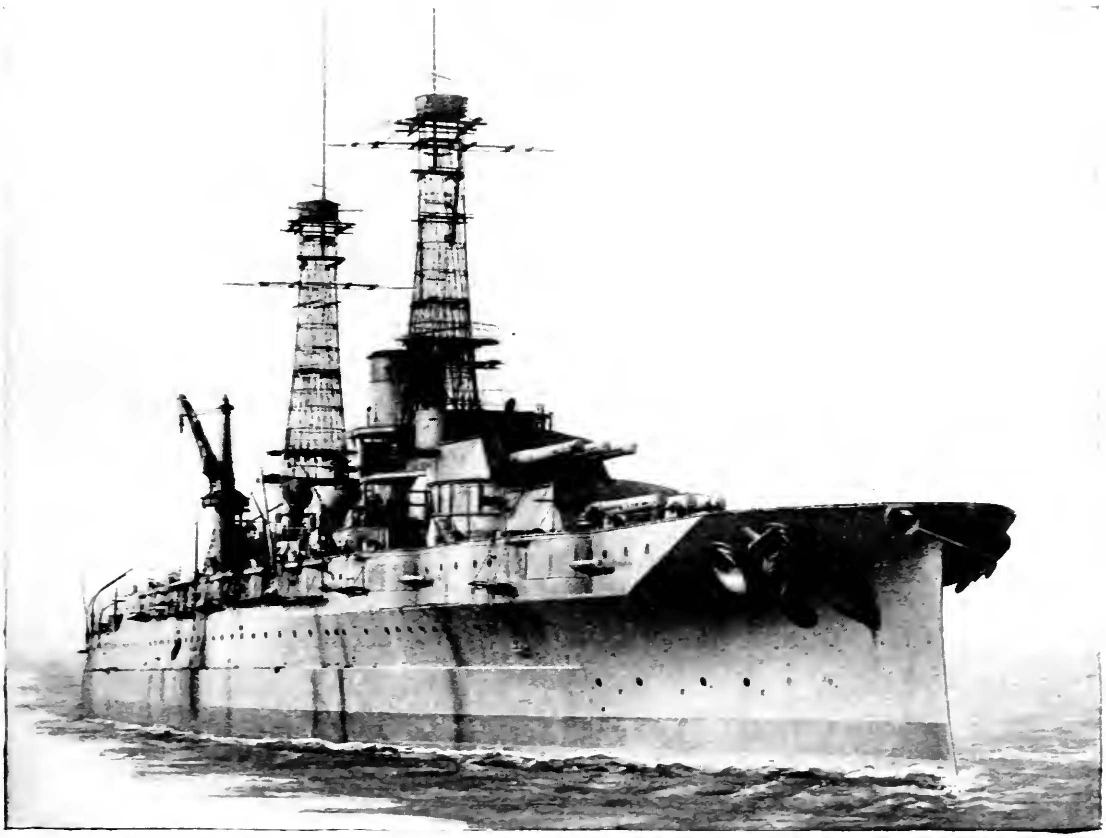
MODERN BATTLE RANGES

The great growth in the possible battle range during recent years has been forced by the increase in torpedo range, which, officially, is now 10,000 yards (5.7 miles), but probably is considerably more.

Since guns can now hit with straddling salvos as far as the fire control officer in the top can see the decks of the enemy ship, the question of the limiting battle range is now in theory one of visibility only—of extending, instrumentally, the range of human vision beyond the horizon which the curvature of the earth makes.

In discussing this subject, Commander Ralph Earle of our Navy gives the distance of the sea horizon from the turret sights as 11,400 yards (5.7 sea miles) in perfectly clear weather. But the "spotter's" platform at the top of the mast of an enemy ship would be about 110 feet above his sea level, and hence would be visible—just above our turret-sight horizon—for a distance of 12 sea miles more, making the total distance of visible objects 17.7 sea miles, or 20.4 land miles (35,400 yards).

However, other conditions than visibility affect this fighting limit. These are, first, the small percentage of hits at extreme ranges; and, second, the wearing out of the guns by erosion of the bore.



Courtesy of *Sea Power*.

U. S. S. Pennsylvania, the Greatest Fighting Ship in the World

The British, during the battle off the Falkland Islands, scored but two per cent of hits out of a total of 750 shots. As to erosion, it is due primarily to the high temperature of the exploding charge and the friction of its gases, although chemical action probably plays a part. With nitroglycerine powder, this temperature reaches 3178 deg. cent. The propelling powder used by our Army and Navy is a low explosive of the nitrocellulose type, which has less tendency to burn out the bore of the gun. Owing to erosion, the accuracy-life of our 12 in., 45 caliber naval guns is but 120 rounds. I am enabled to show the effect of erosion, during a test to destruction, through the courtesy of Major Edward P. O'Hern, U. S. Army, who says:

"The illustration indicates the condition of the interior of a 0.30 caliber machine-gun barrel, after a rapid-fire test of 3000 rounds in which nitroglycerine powder was used. The firings were made with unusual rapidity, and without the presence of the usual water jacket surrounding the barrel."

In view of these facts many gunnery experts believe that, under present conditions, no battle, broadside to broadside, is probable at a greater range than 8 miles (14,000 yards), if closer action can be forced, since no admiral would be justified in wasting his ammunition and wearing out his guns by firing at a greater distance. In chasing, however, guns will doubtless be fired at any range at which a hit is possible.

THE MARKSMANSHIP OF OUR NAVY

A battleship is essentially but a mobile gun platform, and its ability to hit with that primary weapon, the gun, is virtually its sole reason for existence. Occasionally there appear in the press adverse, and usually uninformed, criticisms of the Navy's target practice, of the failures of our "Hitless Navy." The facts, however, as furnished by Admiral Fletcher, tell a different story. In the salvo firing of one of our dreadnaughts in West Indian waters last winter, five shots were fired simultaneously at the same moving target, 30 ft. high by 90 ft. long. The results were photographed. The distance between the extreme splashes in the line of fire was taken as 400 yd.—the maximum dispersion of our projectiles in the line of fire. In one position between the extreme splashes, three shots would have struck a battleship, and in almost any position between she would have been hit by two or more shots.

This salvo was fired at a range of 9000 yards (5.1 land miles), with reduced charges so as to give the same angle of fall as that with a full charge at a range of 16,350 yards (9.3 miles). The hits for these two ranges would thus be the same, since all conditions as to aiming would be identical except the apparent size of the target, which does not matter with the telescopic sight. The firing ship was steaming at high speed, 15 knots. The target was towed at 6 or 7 knots on a non-parallel course, so that the range was changing constantly.

Admiral Fletcher also refers to some later practice, in which one of our ships made seven hits on this small target out of 12 shots. The ship was the battleship *Michigan*. Her commanding officer, Captain Brittain, stated that he opened fire at 18,000 yards (10.2 miles), and continued at an average range of 16,000 yards (9.1 miles). As before, the firing ship was moving at 15 knots and the target was towed on a non-parallel course.

This shooting has not been surpassed—if, indeed, it has been equaled—by any navy, and we are warranted in the belief that the *Michigan* and her consorts are making our dreadnaught fleet the equal of any in the world in marksmanship. The nation hears little of their work in this, since the reports of target practice are confidential. The two examples I have given were revealed only by statements drawn from officers by the House Committee on Naval Affairs.

Cross-Section of a Machine-Gun Barrel After Firing 3000 Rounds with Nitroglycerine Powder

FIRE CONTROL

The accuracy of the target practice which has just been described is due primarily to fire control, which is vital to precision in modern gunnery, and hence to victory in a sea fight. For example, compare the *Michigan's* abnormally high percentage of hits with the similar results at the battle of Santiago. There, under the old hit-or-miss methods, our fleet fired 9000 shots at relatively short range, and made but 120 hits, or 1.3 per cent.

The reasons for this amazing inaccuracy—common to all navies then—were, as Captain Sims says, because "each gun pointer estimated the distance of the enemy for himself, made his own estimate for deflection (*i.e.*, the speed of the enemy across the line of fire), decided at what point on the ship's roll to fire, and how fast his line of sight was moving across the target and consequently how far his line of sight should be off the target (approaching it), when he pulled the lock string. It was because no man could acquire this skill to a high degree, and, particularly, because no group of pointers could acquire it to the same degree, that we could not hit anything except at very short ranges."

The foundation of modern methods of fire control was laid by Commander (now Rear-Admiral) Bradley A. Fiske of our Navy, in his invention and successful application of the telescopic sight to naval guns in 1892. The credit for originating the present system of accurate aiming belongs to Vice-

Admiral Sir Percy Scott of the British Navy. The introduction of this system into our own Navy is due wholly to Captain William S. Sims, who, in 1902—supported vigorously by Theodore Roosevelt, then President—overcame the opposition of the Navy Department, and virtually forced the New Gunnery on the United States Navy—to its great advantage, ultimately.

Fire control, while fairly simple in principle, is complex in detail, and, as it is a progressive art, those details are naturally military secrets. Speaking broadly, the system replaces independent operation of each gun by team work for the whole battery, directed by the fire control officer from the top of the cage mast, 100 ft. above sea level. If this station is shot away in action, the control party shifts to the other mast, or to the conning tower, or, as a last resort, to the turrets.

The general method is: (1) The range of the enemy ship is found by the range finder and its bearing by the gyroscopic compass. (2) Two sets of these observations, with a known interval between, give the data required to compute the enemy's speed and relative course, and the rate of change of range. (3) Instrumental observations are checked by "spotting"—that is, observing the fall of the shell, which usually makes a splash about 200 ft. high, visible in a clear day for 15 miles.

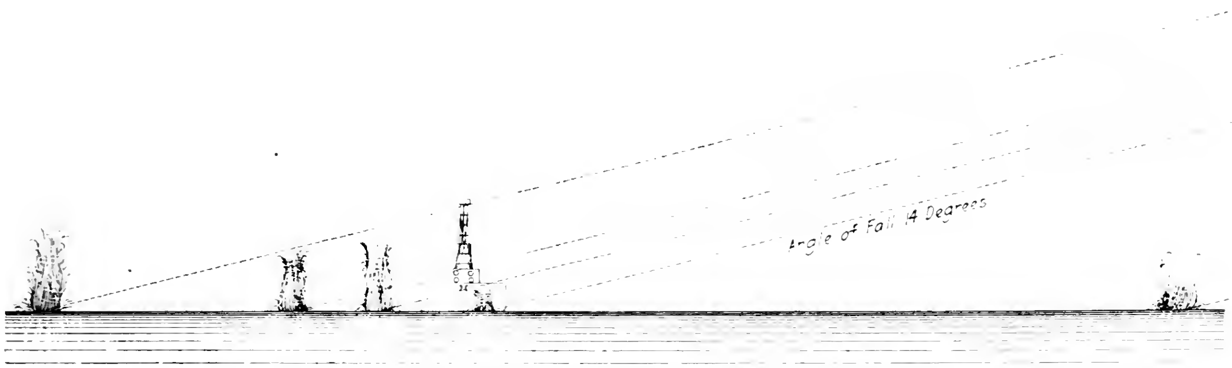
Now, no nation will attack us with any but a dreadnaught fleet, and only dreadnaughts can fight it. Hence, our naval strength lies fundamentally in the number and relative power of our dreadnaughts. At the beginning of the European war Great Britain had, built or building, 38 dreadnaught battleships, of which she has since lost one; similarly, Germany had 20, of which she has probably lost one; and the United States, 12.

As to dreadnaught battle cruisers: Great Britain had 10, of which she has lost 3; Germany, 9, but 3 have been sunk and one sold to Turkey; and the United States, none.

The relative dreadnaught strength of battleships and battle cruisers, based on pre-war figures and deducting losses, is, then: Great Britain, 44; Germany, 24; and the United States, 12.

No one outside of England or Germany knows what they have built or are building since the war started. There have been persistent reports, however, as to feverish energy in ship-building in both countries, and Germany has ample facilities for building at the rate of 25 dreadnaughts a year, while England could probably double this figure under stress.

So the United States has a hard road to travel to reach even second place among the navies of the world. It is true



Effectiveness of Salvo Firing of a U. S. Dreadnaught

(The extreme splashes are 400 yd. apart. In the position shown, three shots would have struck a battleship.)

OUR NAVAL STRENGTH

The battleship has been the backbone of every fleet since navies existed. There is nothing else on land or sea which is its equal in the concentration of enormous power. The energy of one 14-in. shell is, according to Admiral Fiske, equal to that of 60,000 muskets. On this basis, the 12 guns of the battleship *Pennsylvania* are equivalent to the aggregate musket-energy of 720,000 men. Each of her 14-in. projectiles has a muzzle energy of 70,000 foot-tons. Under stress, her main battery of twelve 14-in. guns can be fired about three times per minute—a delivery of 2,520,000 foot-tons during that period.

Essentially, the dreadnaught battleship is, first, an all-big-gun ship—that is, it has a main battery of the same caliber throughout, whose guns are capable of piercing modern armor belts at battle ranges; second, it has a speed of 21 knots or more, so as to be capable of acting in company with other dreadnaughts; third, it has the maximum armor protection which is possible with this armament and speed. The battle cruiser is a modified battleship, having roughly about three-fourths the latter's armament and armor and about 50 per cent more speed.

that, since July, 1914, we have laid down 3 dreadnaughts, that the keels of 2 more will soon be laid, and that 4 more have been authorized for immediate construction. But it takes at least three years to build a battleship or battle cruiser, so that the last of the total of 16 dreadnaughts authorized by the recent Naval Appropriation Act will not be completed before 1922—at which time our dreadnaught strength will be 27, as against the pre-war strength, deducting losses, of 44 for Great Britain and 24 for Germany.

And this is not all. A well-balanced fighting fleet includes cruisers, destroyers, and submarines, in addition to battleships and battle cruisers. The cruiser has two functions: First, the protection of commerce; second, as a scout and for general service with a fleet. In future fleet actions, if we shall not have enough battle and scout cruisers to force the enemy's screen and ascertain his strength and formation, our fleet will be blind and helpless. From all viewpoints an adequate increase in our cruiser strength is imperative, and this increase should far exceed what is proposed now by the Administration and Congress—not by naval officers who know our needs.

The question of destroyers is even more pressing. Primarily,

the destroyer's function is torpedo attack on an enemy fleet in battle. It can act also in protecting commerce and as a scout in moderate weather. But its surpassing service during this war has been in guarding Allied battleships from submarine attack.

England's pre-war proportion of destroyers to battleships was about 4 to 1, and this number she has found far too few as time went on. It takes five of them to convoy a battleship, and it took all she had at first to guard her Grand Fleet off the Orkneys, leaving her 1800 miles of coast line wide open for submarine attack on merchant vessels. To the British lack of these small, swift, and handy craft is due very largely her great losses of merchant vessels.

In 1922 our proportion of destroyers to battleships will be short by about 100 vessels of the British pre-war proportion of 4 to 1. Our deficiency with regard to the present proportion in the British fleet must be far greater. And yet, as the recent raid of the U-53 off Nantucket Shoals proves, we may need them in swarms on our 3000-mile eastern coast line. We might better lack a dreadnaught or an adequate fleet of submarines of our own than a strong force of destroyers.

As to submarines: The coast-defender type has shown its value during this war, and an adequate force of these vessels —not exceeding 800 tons' surface displacement and operating from protected bases—would worry an invading fleet seriously, and force it to make ceaseless attempts to trap or sink its under-water foes.

The fleet submarine—the large boat which, submerged, could charge with the fleet in action—is still but a dream. Her requirements are beyond the present state of the art. The ardent desire of every navy is to have such a vessel, with an engine exhaust which will not leave a white trail on the surface to betray her. She will surely come some day. Captain Simon Lake, the Nestor of submarine inventors, writes me:

"The high-speed submarine is going to come. How soon, I do not know. I do not believe anyone else can answer that question, as it all depends on the engines. Germany is, in all probability, away ahead of us in engine development today, but progress is being made, and as soon as we can get reliable high-powered engines, we shall have reliable high-speed submarines capable of accompanying a fleet."

Admiral Fiske's Greeting

When this paper was projected I wrote to a distinguished officer of our Navy, Rear Admiral Bradley A. Fiske—whose frank and fearless statements as to our naval unpreparedness stirred this country like a bugle-call—and asked him if, in view of the engineer's relation to naval war, he would favor me with a message to this great national body of engineers, through its representatives here assembled. In answer, the Admiral writes:

I am very glad indeed that you are going to address the American Society of Mechanical Engineers on "The Development of Our Fleet and Naval Stations."

There are no other men in the United States so immediately and directly powerful in developing the fleet and naval stations as the engineers. While the strategist estimates the general situation, and determines the application of the general principles of strategy to each situation as it arises; and while the tactician handles the units of personnel and material in actual battle and in preparation for it, it is the engineer who provides the strategist and the tactician with the mechanisms with which to carry out their respective and collective aims.

It is the engineer who enables the strategist and the tactician (and who often forces the strategist and the tactician) to keep his art abreast of the developments of the physical arts and sciences, and to take advantage of them. It is the engineer who has given to the world the gun, the torpedo, the submarine, the battleship, the wireless telegraph, the searchlight, and the aeroplane. It was the original military engineer—the youthful David, afterwards king—who made the first recorded triumph of science and art over mere physical strength, when, at a distance great in those days, he killed Goliath with his sling.

Therefore, for the reason that the engineers of any country have so much power to exert for the safeguarding of their country, and because men are always responsible for the power committed to their keeping, it is the high duty of all American engineers, and of you gentlemen who represent them, so to direct this power as to secure the peace and prosperity of the United States.

With respectful salutations to the Society, I am,

Ever sincerely yours,

(Signed) Bradley A. Fiske.

The Arizona's Quarterdeck, Showing Her Two After Turrets, Each Mounting Three 14-In. Guns

VIBRATION IN TEXTILE-MILL BUILDINGS

By G. H. PERKINS,[1] LOWELL, MASS.

ABSTRACT OF PAPER

The author first states the nature of vibration in textile-mill floors and then enumerates the causes of such vibration, namely, unbalanced machines, heavily loaded trucks, weaknesses of building structure, poor soil conditions for foundations, and sympathetic vibrations originating outside the building.

He then discusses the objectionable effects of vibration in textile mills in regard to the security of the building, the quality of output of textile machinery, and also the nervous systems of the operatives. The methods usually employed in eliminating vibration in an existing building are stated, as well as the precautions to be observed when textile machines are mounted on rigid floors.

In the analysis of specific cases of building vibration, graphical records of the motion produced have proved of much value to the author, and he has accordingly included in the paper reproductions of several such records made by an instrument resembling the seismograph, together with particulars of the building in which they were taken.

IT is the purpose of this paper to outline the principal causes and effects of vibration occurring in buildings occupied by textile-manufacturing processes, with the view of stimulating investigation and promoting discussion on a subject which has received but scant attention from those most vitally concerned. The importance attached to the question of vibration in many other fields of work is strongly emphasized by efforts made for its elimination from high-speed machinery, such as marine engines, steam turbines, electrical machinery and motor cars. Therefore, if vibration of a textile mill can be shown to produce any prejudicial effect on either buildings, machinery, product or employees, it would seem worthy of serious study. Information on this question must necessarily be of a fragmentary character, and nothing is here offered purporting to be a full analysis of the subject. The many and varied influences contributing to the resultant vibration of an entire mill building containing machinery in motion make the problem a complex one, and it is often impossible to even ascribe specific results to specific causes.

Vibration is unquestionably present in every textile-mill building to some degree, although its amplitude may be so minute that it passes undetected either by the senses or by any material effect. While most textile manufacturers will concede that vibration exists in certain parts of their plants, they are rarely convinced that any real damage is done, except when exaggerated or serious conditions affecting production make remedial action imperative. In many of our older mills, extraordinary conditions of vibration have existed for years without apparent serious results. Like conditions of production, except for vibration effects, are so rarely found and so difficult to create, that it is practically impossible to separate the losses due to vibration from those attributable to other causes, or to measure them in economic terms.

NATURE OF VIBRATION IN MILL FLOORS

The physical laws underlying the vibration of simple bodies, such as rods and plates, have been clearly defined and are well understood, but their application to the complex structure of a mill floor will not admit of any simple mathematical treatment. It is well known that all structures, simple or complex, have their inherent periodicity or rate at which "free" vibration will take place when they are set in motion, and that this period is dependent upon the mass, dimensions, and elasticity of the body.

In the textile mill, vibration most commonly results from the unbalanced resultant of forces set up by certain classes of machines, synchronizing to some extent with the natural period of the structure, or of one of its elements, usually the floor. From any evidence available it would appear that the actual movements do not agree, except for exceedingly brief periods, with the "free" natural vibration of the floor and are therefore of a "forced" character. This is doubtless a fortunate circumstance, so far as integrity of the structure is concerned, and cases are rare where vibration has been the direct cause of a building failure. The historic Pemberton Mill disaster occurred in a building noted for its freedom from vibration.

Two distinct classes of movements are commonly found in textile-mill floors:

a Horizontal movements of floor, more or less independent of walls, of comparatively low frequency and large amplitude. These may properly be classed as oscillations.

b Movements of higher frequency and less amplitude, often in a vertical plane, which may be considered as no more than tremors.

While vibrations may exist in all three planes simultaneously, they are under textile-mill conditions more apt to be strongly emphasized in only one direction. These motions may properly be considered as truly harmonic in character, and their period, frequency and amplitude defined as from a sine curve.

CAUSES OF VIBRATION IN TEXTILE MILLS

The principal factors contributing to vibration in textile-mill buildings are:

I Unbalanced machines, of which the following are the most important:

a Looms. The lay and pick motions of practically all looms are unbalanced reciprocating movements in a horizontal plane. Harness motions, including Jacquard heads, are reciprocating movements in a vertical plane. The frequency of these motions ranges from 90 to 180 picks per minute, depending upon type of loom and class of work.

---

[1] Head of Textile Engrg. Dept., Lowell Textile School.

Presented at the Annual Meeting, December 1916, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Pamphlet copies of complete paper may be obtained without discussion: price 10 cents to members, 20 cents to non-members.

b Noble worsted combs. The dabbing brushes are actuated by vertical reciprocating motions at from 1000 to 1200 r.p.m., with two brushes per machine. Cotton combers, on which the nipping motion oscillates at from 100 to 125 nips per minute, giving slight vertical throw.

c Mules. The carriage of a mule moves with a variable alternating motion in a horizontal plane at from 4 to 6 draws per minute.

d Unbalanced drums, cylinders, rolls and pulleys are frequent causes of local vibration. Worn or defective gearing also often causes trouble on heavy roll drives, as on calenders.

e Heavily loaded trucks moving over light floors cause deflection of beams and plank and some vibration.

II Inherent weaknesses in the structure, such as thin walls, light floors with long spans, and unsuitable connections between floors and walls.

III Poor soil conditions contributing to relative freedom of foundations and footings.

paper will best be served by confining the results shown to those obtained from one typical weaving mill.

Length, 270 ft. 0 in.	Spans: 4 of 26 ft. each
Width, 116 ft. 0 in.	1 of 12 ft.
Basement, 10 ft. 6 in.	Bays, 7 ft. 6 in.
Two Stories, 16 ft. each	Roof of Saw-Tooth Type
Walls: 24 in. on first story, 20 in. on 2d story	
Pilasters, 28 in. wide	Windows, 5 ft. 0 in. wide
Floor Beams, 10 in. by 18 in.	Floor Plank, 4 in.

Floor plans and arrangement of machinery are shown in Figs 1 and 2. Stations at which records were taken are numbered on floor diagrams. It will be noted that all looms are arranged across the mill and records show longitudinal vibration only. Records taken with instrument set transversely showed no appreciable motion on either floor.

Records taken in this mill after the installation of additional looms, indicated a decrease in the maximum amplitude, fewer cyclic variations and a somewhat higher average amplitude. (See Figs. 3 to 7.) The reduction in the maximum

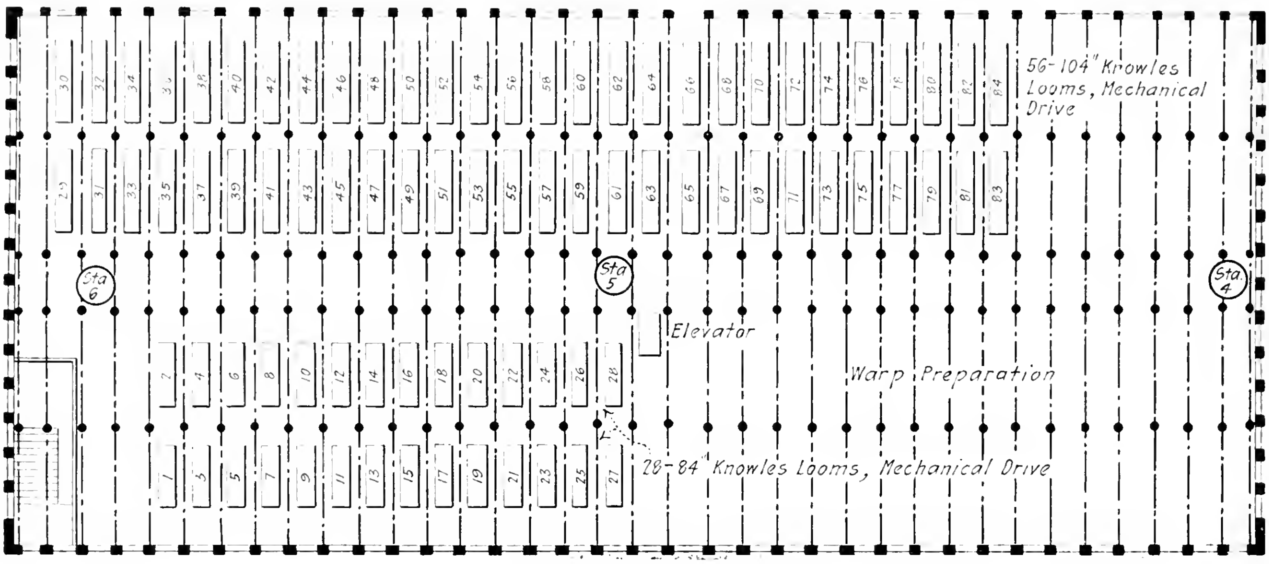

Fig. 1 First-Floor Plan

IV Sympathetic vibrations originating outside the building. These are frequently set up by water falling over dams, reciprocating engines in adjacent buildings, or by railroad trains. Their mode of transmission is often obscure, although it is sometimes direct, as through pipe lines or solid ledge.

VIBRATION RECORDS

In the analysis of specific cases of building vibration, graphical records of the motion produced have proved of much value. Such records showing the period, amplitude and cyclic variations of the vibrations serve as a guide in tracing their origin and assist materially in estimating the effects produced on building and machinery. Numerous instruments for this purpose, which need not be described here, have been constructed, involving the basic principle of the seismograph originally developed for the study of earthquake phenomena.

The partial records presented are portions only of results obtained in the course of investigations carried on under various conditions in textile-mill buildings. As it is obviously impossible to present any extended records, the purpose of the double amplitude was from 0.059 in. to 0.045 in. This is not an unusual experience when mills are equipped in installments. A mathematical analysis of the unbalanced horizontal force applied to the floor by a 72-in. Knowles worsted loom running at 120 picks per min. showed an average value of 154 lb., with a maximum of 262 lb. This gives some conception of the magnitude of the total force acting when a number of looms are in synchronism.

In all cases any movement estimated by the senses was far greater than actually recorded. This bears out the fact that even small and harmless vibrations are often responsible for apprehension on the part of the operatives.

EFFECTS OF VIBRATION

In presenting information covering the effects of vibration, the writer wishes to acknowledge the assistance rendered him by the Aberthaw Construction Company, of Boston, Mass., who deserve much credit for undertaking an extensive investigation of this unpromising subject. They have placed at the writer's disposal all of the interesting material accumulated by them to date, covering a wide range of industries.

Objectionable effects of vibration in textile mills have been noted by various observers as follows:

a Settling of foundations and footings on poor soils, with resultant cracking of walls and unleveling of floors, due to a "shaking-down" process of buildings subject to excessive vibration.

b Effect on operatives. This is usually manifested by apprehension of the failure of the building, loss of efficiency due to fatigue, and the serious effect of continued vibration on the nervous system.

c Effect on production of textile machinery.

Carding Wider card settings are found necessary on vibrating floors, causing uneven and poor work.

Spinning Vibration of ring rails on frames spinning either fine numbers or coarse waste yarns, causing breaking down of ends.

Turning of roving bobbins on skewers of spinning-frame creels, causing roving to unwind and kink.

"Chatter" of rolls on long frames.

Weaving Vibration of tension weights on narrow fabric looms, causing dropping of weights when loom is at rest.

Shaking of similar tension weights on elastic-webbing looms, permitting rubber warp to slacken and causing defective work by allowing excess elastic to enter fabric.

Increased sensitiveness of "feeler" mechanisms in filling changing looms.

Finishing Chattering of "doctor" blades on "backfilling" mangle, due to passing trucks, causing uneven distribution of starch on goods and imperfectly cleaned roll.

Wave movement of water in pan of "damping" machine, causing uneven distribution of moisture on goods by spraying brush.

Miscellaneous Breaking of electric-lamp filaments, making spring suspensions necessary. Difficulties in use of sensitive instruments, such as balances, scales, testing apparatus, etc.

Many consider that the matter of increased power consumption of shafting due to vibrating floors is important, but no authentic tests covering this point are available.

ELIMINATION OF VIBRATION

The elimination of vibration of an existing building of mill construction is usually attempted by:

a Stiffening and strengthening of floors by additional columns or trusses and making more secure connections to walls; also by stiffening outside walls with additional pilasters, or in the case of wooden-frame buildings even by braces or guys.

b Balancing of all machines possible and cushioning or absorption of the shocks of machines in which an unbalanced component seems unavoidable. More attention could advantageously be given to the matter of balance in certain classes of textile machines by their builders. Incidentally, the attendant reduction of noise would be beneficial.

The well-known advantages of reinforced-concrete buildings with particular reference to rigidity will not be discussed here, but such construction undoubtedly would obviate a large portion of the difficulties outlined above. There are certain conditions, however, where too great rigidity has been found to be most undesirable for certain classes of textile machinery as at present constructed. Such a large proportion of our textile plants occupy buildings of "slow-burning" mill construction that it is the present purpose to show existing conditions rather than emphasize the advantages of any one type of construction.

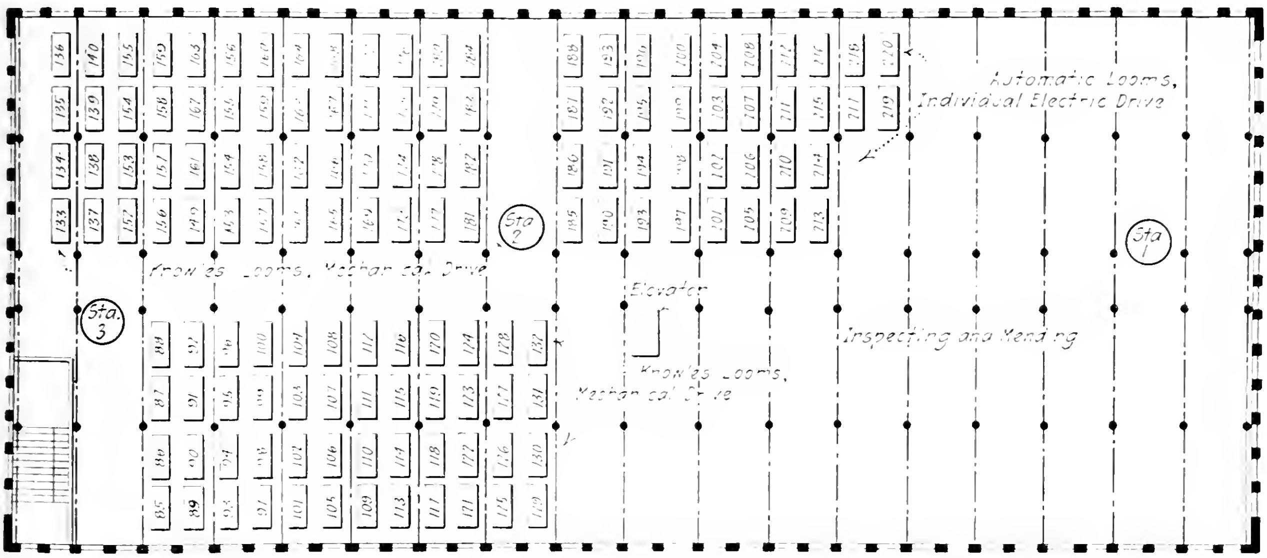

Fig. 2 Second-Floor Plan

EFFECT OF RIGID FLOORS ON TEXTILE MACHINERY

The data available covering the comparative operation of textile machinery under similar conditions on rigid and flexible floors are extremely limited, but experience seems to emphasize the following:

a In weaving heavy fabrics, the breakage of loom parts has been excessive when looms are mounted on concrete floors with no provision for absorbing the shocks produced. Cushioning the loom feet with absorbents such as wood, cork or rubber, has been found absolutely necessary under these conditions.

b Transmission of the noise of machinery to offices, laboratories, etc., has been found exceedingly annoying in some concrete buildings.

NEED FOR FURTHER STUDY

The problem of mill vibration, while not new, has yet to receive either full recognition or sufficient serious attention. The resulting economic losses are unquestionably large, if analyzed from all standpoints, and the elimination of vibration is consequently an important factor in the efficiency of the plant.

All information at present available would seem to point to a general agreement as to the desirability of avoiding excessive vibration in manufacturing buildings. There is evidence of a growing interest in the subject, but the scarcity of authentic results from experimental work along this line, carried on under actual manufacturing conditions, makes exhaustive tests and observations necessary before any general conclusions can be reached.

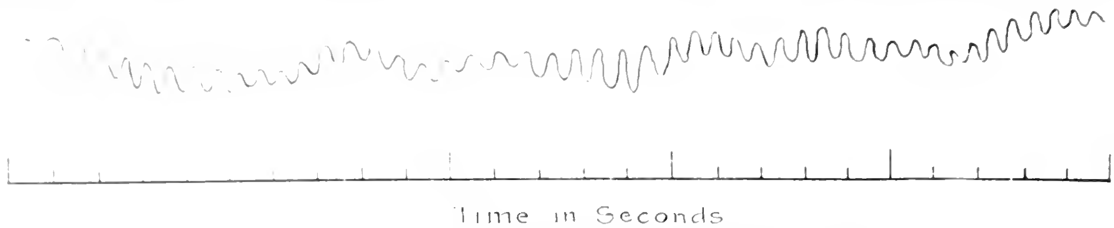

Fig. 3 Record No. 1, Taken at Station 3 on Second Floor

Shows High Average Amplitude. Period, 108 to 120 per Min. Average Loom Speed, from 110 to 120 Picks per Min. Maximum Double Amplitude, 0.03 In.

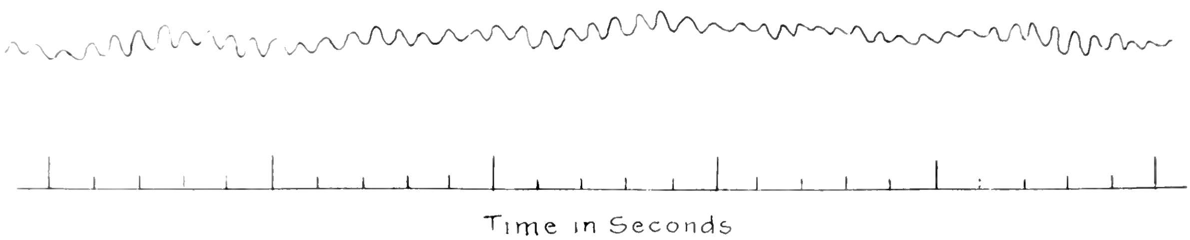

Fig. 4 Record No. 2, Taken at Station 3 on Second Floor

Shows Low Average Amplitude under Same Conditions. Records Taken at Station 2 Showed Same Characteristics as Those at Station 3

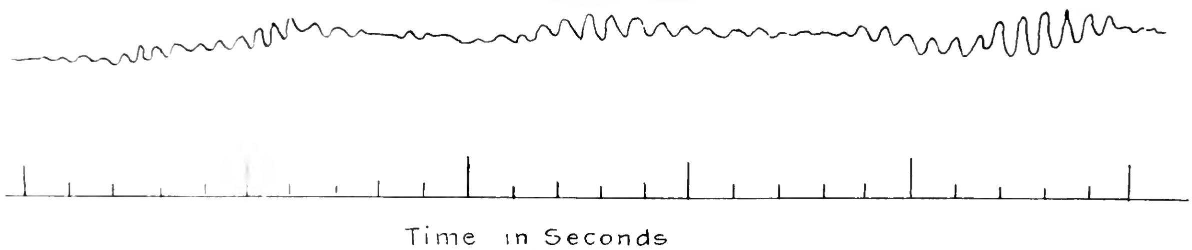

Fig. 5 Record No. 3, Taken at Station 3 on Second Floor

Shows Evidence of Cyclic Disturbances about Every 8 to 10 Sec.

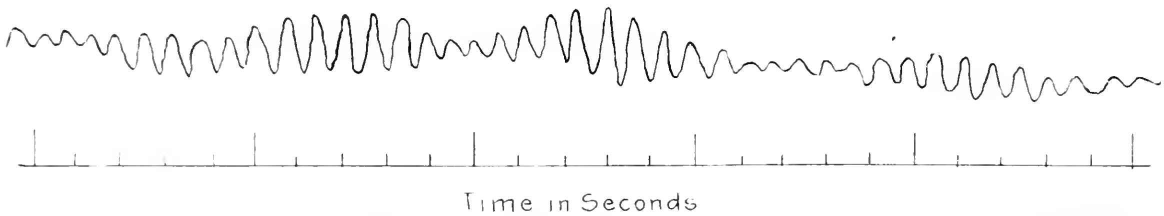

Fig. 6 Record No. 4, Taken at Station 1 on Second Floor, About 50 Ft. Away from Nearest Machine

Indicates How Readily Vibrations are Transmitted through Floor Undiminished in Amplitude. It may be Noted that the Group of 36 Looms Nearest to Station 1 are Individually Electrically Driven. Maximum Double Amplitude 0.045 In.

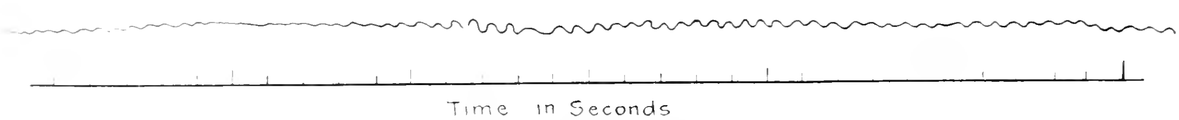

Fig. 7 Record No. 5, Taken at Station 5 on First Floor

Shows Typical Record at this Point with Vibrations of Slightly Less Frequency and Small Amplitude. The Average Speed of the 104-in. Looms on This Floor was 90 Picks per Min., and the Speed of the 84-in. Looms was 98 Picks per Min.

HOW DOES INDUSTRIAL VALUATION DIFFER FROM PUBLIC-UTILITY VALUATION?

By JOHN H. GRAY,[1] MINNEAPOLIS, MINN.

IT IS my object in this paper to show that value logically and necessarily means exchange value based on capitalized earnings, real and estimated. It depends on strategic advantages, and involves speculative elements, which are destroyed when an industry is declared a public utility and its earnings are limited to a fair return. This fair return has no relation to value, but is a matter determined in the supposed interests of the public welfare. The basic purpose of regulation is to limit profits to a just amount, and thus to take that part of the property for the public which would inure to the private owners under non-regulation. For the value of such an unregulated private monopoly is limited only by the willingness and ability of the people to pay rather than do without the services of the monopoly.

This paper deals chiefly with valuation of public utilities for purposes of fixing rates. As the courts ruled in 1898 that utilities are entitled to a fair return on a fair value of property in use at the time of valuation, valuation is necessary if regulation is to be attempted.

The most significant tendency of the last two decades the world over, and more particularly in America, has been toward the socialization of wealth; or, to express it in another form, toward the limitation of the rights of private property. Many businesses formerly considered private—gas, electricity, common carriers, insurance, banking—have now been brought under public regulation.

For better or worse, public utilities have been taken out of the category of unrestricted private property. Technically, they remain private property, but the law has taken from them the chief attribute of private ownership, that of the chance of speculative gains. The doctrine of fair return forever separates such property economically from ordinary private property.

For instance, it is only a single generation since the courts of this country uniformly declared that the making and distribution of gas was a private industry. The most conservative would not undertake to maintain that view today. The placing of electricity within the class of public utilities is much more recent. But, perhaps, no other industry illustrates this point as well as the common carrier and the extent of regulation, which, in theory, is universally recognized as proper today, compared with that which we considered permissible a generation ago. A mere study of the phrases "reasonable rates" and "unjust discrimination" will show the progress we have made, for good or for ill, along this line.

The same social progress has brought urban land, and in some countries all kinds of land, under special public control in every civilized country except America. What is true of land is equally true of the whole range of insurance. The changed attitude of the public mind towards the rights of banking illustrates the same point. A century and a half ago banking and insurance were, both, under the common law, occupations freely open to anyone, without restraint.

REASONS FOR CLASSIFYING CERTAIN INDUSTRIES AS PUBLIC UTILITIES

We have found that social considerations make certain industries of more immediate and overwhelming interest to the public welfare than are ordinary private businesses, and have thrown them into a single category labeled "public utilities"; but what social, economic and political reasons justify us in so doing?

About 150 years ago there grew up the theory that under a system of free competition one's self-interest would prevent him from injuring the public. With an abundance of free land, large opportunity to expand, accompanied by a high degree of intellectual, social, and educational equality, this was measurably true. But with the creation of fixed capital on a large scale this doctrine became unsafe, and self-interest can no longer be depended upon to hold in check the recklessness, greed and extortion of the owners of even purely private property. Government regulation may then be ascribed to the breakdown in the application of competition.

If competition, as indicated, is not a real safeguard, what is the danger of leaving private parties unrestrained in those industries where competition no longer works smoothly or effectively? I think if we go thoroughly into this point, we shall realize as never before that with the limitations of human knowledge the more complex the machine became, the more extended the division of labor, and the larger the mass of fixed capital, practically the more dangerous to the public was any mistake of the owners. If we wished to turn this into a modern phrase, we should say that it was strictly the speculative element in private property, the buying and selling and holding for an increase in price, that furnished the point of greatest danger. One was allowed this freedom in the early days on the supposition that the natural resources and things out of which property rights could be carved were virtually unlimited, and that when one undertook to develop these resources and claimed them for his own, he was doing a public service. Since we have found that resources are not unlimited and that we must learn to live together, we have discovered that, in this particular, what one gets for himself is taken from another, or at least prevents the other from taking in like manner and to the same extent. In other words, we are face to face with monopoly.

The world has now become alarmed on the subject of non-regulated privately owned monopolies, and there is a growing tendency to declare more and more of these to be public utilities. We apparently have reached the conclusion that civilization cannot be maintained or advanced unless such utilities can be made to render adequate service at a reasonable charge and without unjust discrimination. But increasing emphasis must be put on the fact that stability, regularity and universality of service are of infinitely more importance to the public than the general level of charges or the amount of profits made by a company.

SPECULATIVE ELEMENT IN PUBLIC UTILITIES THE ULTIMATE REASON FOR REGULATION

In the past the reason for the purchase of property has

---

[1] Professor of Economics, University of Minnesota.

Presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, December 1916. The paper is here printed in abstract form. Pamphlet copies of complete paper without discussion may be obtained; price 15 cents to members, 30 cents to non-members.

often not been merely for the sake of income, but for the sake of possible gains in selling. Whatever we may finally consider is justice in regard to the reckless, unsavory and speculative past in this field, we may safely say that the world has now come to the view that for all future investments the amount contributed by the owners shall be the basis of calculations for rates, and that variable risks shall be met by varying rates of charge and income rather than by fluctuations in the value; for so long as we have the latter, owing to false valuations, we shall have manipulation and speculation to bring about increased gains. Our present problem is how are we going to take conditions growing out of competitive circumstances and adapt them to an age of monopoly with as little friction and injury as possible, and, in working it out, we must never forget that speculation and regulation cannot simultaneously exist.

LIMITATIONS IMPOSED ON PUBLIC-UTILITY PROPERTY

We are here concerned with the meaning of the content of the term "property": what are, in fact, and what ought to be, the limitations, if any, on the absolute rights of property. Are the limitations on public utilities different from those on strictly private property, and are they more severe? There can be no doubt of the present tendency on this subject. It is all towards greater socialization of wealth and limitation of private rights. One evidence of this is the growing tendency towards public ownership and operation, and the public enjoyment of property shows this. The constant enlarging of the list of industries that are subject to more and more restrictions in the public interest clearly points in the same direction.

It is true that many such industries are comparatively new, but they existed for a relatively long time before they were classified as public utilities. For instance, the common carrier is old; and it took us a long time to realize that the parlor-car business, the pipe lines (gas and oil), gas companies, the telegraph, the telephone, fall into the same class because of performing similar functions, and, that, if left unregulated, they are capable of inflicting like monopoly injury and abuse. So we have progressed step by step from the common carrier through the utilities named to the street railway, the use of electricity in all its manifestations, to conduits, cold-storage warehouses and the like. Furthermore, we have recently entered upon a broad and wide field, with ill-defined limits, that comes neither within the realm of public utilities nor private property, as these terms have heretofore been used, but occupies what Mr. Bryan calls a "twilight zone."

Justice Brewer discusses such cases in the Kansas City Stock Yards case,[1] where he considers various industries requiring some special regulation, but not such as we impose upon public utilities. One cannot view the progress regulation has made, for good or for ill, without realizing that the emphasis on property rights has changed fundamentally in recent years. In the opinion of this generation, property either public, semi-public, or private is looked upon more and more as a public trust. The attitude of the public mind, and of the law, has not only changed toward the industries mentioned, but has changed towards the industrial trusts as well; hence our anti-trust laws. Recently we raised the question whether mere size is cause for added regulation. For an answer to this question we must wait for the Harvester case to be decided. The subject naturally shades off into pure-food laws, building ordinances, height of buildings, and so on.

[1] Cotting v. Kansas City Stock Yards, 22 Sup. Ct. Rep. 30 (1901).

THE FAIR VALUE OF PRIVATE INDUSTRIAL PROPERTY

The question of the fair value of a strictly private (industrial) property depends principally on what it will actually sell for. This is determined by the actual past earnings and an estimate of future earnings, the latter being based on a presupposed established rate of charge. If the property is not subject to effective competition, the only way of arriving at its value is to estimate what it would sell for under competitive conditions.

This argument rests upon the *laissez-faire* doctrine of competition. The idea of competition rests on the right of charging all the traffic will bear, and on the assumption that natural forces place a limit to charges and thus prevent extortion. In such cases no government regulation is necessary or desirable. Regulation is the very antithesis of competition. The necessity for regulation comes from the fact that competition is totally absent, or is ineffective to protect the public and keep charges within the bounds of reason and in harmony with the welfare of society.

I have gone into this long preliminary statement to furnish a proper background, or foundation for our discussion, and to show, also, that things are not as hard and fast as we have been wont to suppose, and that changes in our legal system, even without any changes in the constitution, are not so difficult as they have usually seemed to be. But let us now come back to the main issue.

HOW SHOULD A PUBLIC UTILITY BE VALUED?

Since the monopolies under question are not sold frequently enough under comparable circumstances to establish a market price, we estimate the value on the basis of capitalized earnings, and on the (legal) assumption that the existing rates are fair and just.

There is a legal assumption that the existing rates are just, because they have not been judicially called in question or proved to be unjust. Take, for example, the vexed and admittedly unsettled claim of the public to a share, at least, in the clear surplus of a company acquired out of earnings which have also yielded dividends at a fair rate. It is conceivable that the question might properly be decided one way in the case of a company going out of business, and in exactly the opposite way for a company compelled to continue to serve the public, or, one way in regard to a surplus acquired before the era of regulation, and quite another way in the case of a surplus accumulated under regulation. In the one case the rate from which the surplus came might be considered both legal and just, in the other as both illegal and unjust.

But all careful and disinterested students now recognize, notwithstanding great vacillation of the United States Supreme Court on the subject, that the necessity for this super-regulation arises solely from the fact that the industries now under review are monopolistic. It cannot be said too often that regulation is simply a substitute for competition.

Gains due to speculations, stock waterings, frauds, extortions, excessive charges, surplus and unearned increment ought not to be and cannot be allowed to go to owners of public utilities. Past claims ought to be compromised or adjusted in some way and a new start made on a sound basis. With a complete, amicable and final settlement of this question, all

would agree that all that owners of public utilities are entitled to in the future is a safeguarding of the money they contribute and an annual rate of income commensurate with the risk involved.

PUBLIC-UTILITY PROPERTY ENTITLED TO A FAIR RETURN

Public-utility property, being devoted to public use, must be content with a fair return, determined under our system of jurisprudence by public authority, with an ultimate appeal to the judiciary. It is liable for continuous service, additional investment may not be made without specific consent of the public, accounts must be kept and made public in reports, and the owner must serve all alike without discrimination. Ownership under such conditions of incumbrance is therefore but partial.

The novel theory has recently been put forth that public-utility property is not in fact dedicated to public use, but merely the service is so dedicated.[1] But this theory in view of all the facts seems scarcely tenable. Such a limitation amounts to the statement that the property as compared with private property is property affected with a genuine servitude or incumbrance. If one has incumbered his private property with a mortgage, he does not expect to enjoy as large a net income therefrom as if the property were wholly unincumbered. Just so, on investing in public-utility property one does so under the present law and practice of regulation, with full legal notice of this incumbrance of regulation. To this extent, and in this sense, he is not free to do as he pleases with his own if he professes the public service.

We must not lose sight of the fact that freedom of contract is at the very foundation of all property rights, and cannot in essence or in law be separated from property as protected by the fifth and fourteenth amendments and other constitutional provisions. Nor would I be understood to say, or even to imply, that these constitutional safeguards are of no significance in the case of public-utility property. The whole point of my argument, however, is, that, by declaring certain property affected with a public interest, we have thereby necessarily given such an interpretation to these constitutional provisions as seriously to incumber the property, and, therefore, have restricted the uses to which it can be put so long as it is dedicated to a public use.

VALUATION OF FRANCHISES

Under our system of law a secondary or local franchise is property, but it is not to be valued, in ordinary rate cases, unless there is some specific agreement or contract on this point that makes valuation necessary. Unless a franchise gives an exclusive right and carries an inviolable contract for a fixed charge, it is not to be valued in a rate case under the established principles of regulation. The general rule now is that in rate cases franchises are not to be valued above actual cost. This is plain from the mere fact that in a rate case the fairness of the present income is the point at issue.

Valuations are made today not because justice or economic policy require it, but because of the court ruling that property is entitled to a fair return on its fair value. What is a fair value? These industries are vitally necessary to us, and if left in private hands the estimated income from them must be at the normal rate in the community for investments accompanied by like risks, in order to attract the necessary capital.

In a rate case it is impossible to arrive at a valuation that has significance. Courts have tried in vain to qualify value by such words as "fair." If these words could be collated and disconnected from their speculative past, they would mean simply that a company is entitled, in view of the unregulated results of the past, to what the court, under all the circumstances, regards as an adequate reward for the services and capital the owners have wisely and efficiently contributed. This, however, has no fixed, permanent or measurable relation to value in an economic sense.

COST-OF-REPRODUCTION THEORY OF VALUATION

For a decade or more and until recently the so-called cost-of-reproduction theory of value actually dominated courts and commissions, but they now demand the facts of investment. Companies claim a value on the cost of reproduction as high as the public would be willing to give rather than forego the service and undergo all the inconveniences of doing without it until a duplicate plant could be built. They forget, however, that the public, in absence of specific contract, has a right to duplicate the facilities, and that this would greatly lessen, or even destroy, the value of the old plant.

The fact that in a majority of the older and stronger railroads and many other utilities the original water has been squeezed out by the investment of surplus earnings in the plant, does not simplify the problem of valuation but merely adds complications to it. It emphasizes all the more the speculative elements in the situation. In the earlier days, the companies claimed a return on all their watered stock, and opposed regulation that interfered with this claim. To this the court answered with its "fair value." The effort of the companies was to inflate the valuation so as to bring about the results that the court denied them in the case of Smythe *v.* Ames. Meantime, social growth was very rapid and regulation very lax. Therefore, when prosperity came, surplus was piled into the plants in addition to a fair dividend, and under the doctrine of valuation and freedom of contract the companies with such surpluses based their claim to these same old speculative gains—gains which may legally, if not wisely, be permitted to go to private property, but which the law of public utilities tried to prevent from coming into being, and, by its doctrine of reasonable rates, tries to claim a share in after they have been created. I am not, at this point, passing judgment on the question whether these speculative gains ought to be prohibited or not. I am simply trying to show that the idea of monopolies regulated by law, under the doctrine of public utilities, leaves no place for them. The main object of classifying any industry as a public utility is to prevent this very thing. But valuation under the cost-of-reproduction and similar methods now employed prevents the accomplishment of this object through regulation.

All our trouble with regulation comes from past speculation and not from an inability to agree about what is just and fair, so far as entirely new utilities and future investments in old ones are concerned.

RESULTS OF CURRENT VALUATIONS MISLEADING

The valuation of all the railroads now in progress, as well as current valuations in rate cases, are worth more than their cost as a means of educating the public, and may be highly profitable as a basis for compromising with the companies

[1] Jared How, Discussions of the Economic Club of San Francisco, vol. I, p. 44.

for their past efforts. But they do not arrive at value in the economic or market sense. They are misleading, for the public supposes that on the theory of the cost of reproduction the next time a rate case arises we must go all through the process again, and drag in all the speculative elements due to social growth, unearned increment, and the like.

It may not be out of place to call attention, at this point, to several relatively recent street car franchises[1] based on the so-called principle of cost of service. These franchises are all in my judgment not only defective but vitally defective. But they are worth all they have cost and all they will cost in the future because of their contribution to the particular point under discussion. They have banished, once and for all, from these systems the bugbear of valuation; for the future the amount on which the companies are entitled to a return is the actual investment, or what is accepted as such by agreement.

These franchises are meant to give a fair return, in the future, on public-utility investments, made on a monopolistic basis, under non-speculative conditions, and publicly controlled capitalization.

Unless an attempt at regulating capitalization by commissions should prove as futile as earlier attempts at preventing stock watering have heretofore proved, investments made from now on will need no valuation whatever in these cities or elsewhere in rate cases. Furthermore, it seems plain that all commission laws will, in the future, provide for controlling investments and capitalization. It is not too much to hope and expect that the Interstate Commerce Commission will, at an early date, be given power over these matters.

This is what the new model franchises call for. It is what sound regulation means. It still leaves the vexed question of pioneering past wrongs and extravagant ventures to be settled by compromise, not by determining value in any proper or economic sense of the word. As previously stated, this is a matter of public policy, to be determined not by experts but ultimately by public opinion.

Any other method of trying to determine what is fair to the owners by valuation, or otherwise, plunges us at once into the question of how to deal with the results of past speculation, good, bad, and indifferent. How ought the punishments and the rewards of these past reckless, unregulated conditions of the competitive era to be apportioned between the owners and the public? What is a reasonable notice of a profound change of policy on the part of the government? There can be no doubt of the legal right of a government to change its policy and as little doubt of the fact that by creating the class of public utilities and making them subject to such regulation as the law calls for, we meant to change the relation of this property to government and to take away the chance of speculative gains. Is it fair then to enforce these laws strictly, or should we give more time for adjusting the old conditions to the changed ideas of public welfare? In other words, when ought we really to begin to enforce the theories underlying regulation? I cannot undertake to answer these questions at this time, but content myself with remarking that we have allowed the owners in their attempts to safeguard their supposed interests through valuations, to make control of future investment practically impossible, while contributing almost nothing to the settlement, under a compromise agreement, for the chaos of the past.

[1] I refer more particularly to the so-called street car settlements in Chicago, Cleveland, and Kansas City.

THE SURPLUS PROBLEM

If we could imagine all public-utility property now existing wiped out by a miracle, and all other things to remain as they are, namely, knowledge and needs, does anybody imagine that any question of valuation or "fair value" would or could arise? Under the present form of commission control, the commissions would simply see that the money with which to rebuild was properly capitalized, and the owners would agree that their returns ought to be based on this amount, and no other. Sound regulation aims at stable and equal rates much more than at low rates or low profits.

As for the claims of the public to a share of the surplus, the commissions would take charge of that at its source, and, under their control over investments, see to it that only such future surplus ever came into being as was really needed to protect the credit of the company and to carry on the business effectively. We should have no such a condition as presents itself today in the Union Pacific Railroad, which as a result of successful speculation now holds securities of other roads to the amount of \$175,819,947; and in addition, a surplus in cash, and cash items, of \$35,000,000. If the road never did any more transportation business or utilized any of its transportation property for any purpose, it could, from its other investments, pay a good dividend on its common stock in perpetuity. What relation has all this property to a fair rate? What is a fair valuation? What property ought to be included in a valuation of the property of this system?

Probably any system of effective regulation calls logically for a guarantee by the public against all losses necessarily incurred. It might be more advantageous to do this directly and openly instead of as at present inflating valuations under the heads of "going concern," "cost of developing business," etc.

CONCLUSION

To summarize: The welfare of the public has made it necessary to class certain industries as public utilities and to limit their profits. In the absence of regulation there would be no limit to the profits except the ability of the public to pay. Value, in the ordinary sense of the word, would therefore increase. The chief motive for regulation is to prevent such possible extortion by confining utilities to a fair and steady rate. This, however, destroys those attributes of private property out of which value grows. For value is measured by earning power, and this under regulation is fixed by law and not by the economic forces and bargaining power that fix value in the only proper meaning of the term. Therefore, to attempt to discover value as a means of fixing a rate of such a monopoly is to reason in a circle.

We have been led into this slough of despair in the wrangle over who ought to have the gains and who ought to bear the losses of the era of competition. With these questions settled once for all, there would remain no controversy over the fact that the amount so agreed upon plus any future additions is the investment upon which a fair return should be allowed. The present commission system of regulation, with its power over investments, capitalization and accounts, provides for such determination of the investment, and there is now no possible chance or occasion for valuation for rate making under such an arrangement, except as the controversy over the disposition of the speculative gains of the unregulated past and the uncertainty of the records of that period make it necessary as a basis for compromise.

REPORT OF COMMITTEE ON RECOMMENDED PRACTICE FOR STANDARDIZATION OF FILTERS

On January 28, 1913, P. N. Engel, Mem.Am.Soc.M.E., suggested in a communication that the Society appoint a committee to take up the question of rating of mechanical filters. Mr. Engel's suggestions were substantially as follows:

"Mechanical sand filters of the pressure type are coming into more general use every year, and yet the engineer or architect under whose specification they are bought and installed has no way of ascertaining just what size filters are needed to perform a certain amount of work, other than he can secure from the various filter manufacturers' catalogues, or from the claims of the filter salesman, which we regret to say in many cases vary greatly.

"Practically all of the standard filter manufacturers are agreed that a square foot of filter surface will not perform more in one filter than it will in another, with equal efficiency.

"I believe that the members of your Society will be greatly benefited by having an approved specification to which they could refer when buying filters, and therefore respectfully suggest that your Council appoint a committee to investigate the matter and to recommend the adoption of a standard specification.

"The points established are that the capacity of a filter is governed by the filtering area—that the filtering area is governed by the internal horizontal diameter of the filter; that all filters of a given diameter have the same capacity; that the capacities of filters of a given diameter vary according to the efficiency desired; that the more slowly the water passes through a filter, the more perfectly will the water be filtered, the minimum rate of flow being 2 gal. per sq. ft. of filter area.

"A standard specification will mean that the buyer of a filter of a given capacity will get a filter of the proper size—no matter from which manufacturer he buys it, and this is not the case at the present time, as the mechanical engineer has no text-book or standard specification to tell him what size filter is needed."

Mr. Engel's letter was referred to the Council, who in turn consulted a number of experts in this field on the desirability of the Society taking action in this matter. The consensus of opinion being favorable, the Council, on May 12, 1913, appointed the following committee to investigate and report on how to rate the capacity of mechanical filters: George W. Fuller, Consulting Engineer, *Chairman;* P. N. Engel, Vice-President, International Filter Co.; J. C. W. Greth, Manager, Water Purifying Department, Wm. B. Scaife & Sons Co.; James C. Boyd, Managing Engineer, Westinghouse, Church, Kerr & Co.; Wm. Schwanhausser, Chief Engineer, International Steam Pump Co.

For some time the work of the committee served to emphasize somewhat the importance of the conditions that led to its appointment, while at the same time developing difficulties in the way of making an adequate report.

The committee found, upon investigation, many points which undoubtedly needed remedying, it being doubtful whether pressure filters as used in the mill business or in the office-building business could be further standardized to approach the basis used in the best offices for municipal standards. The small pressure filters did not seem capable of having attached to them the various safeguarding devices used in the larger city plants.

On August 7, 1915, the committee lost by death one of its members, Mr. J. C. W. Greth, who rendered much aid in the collection of data on the practical side of the art. The chairman called in two new members, Arthur M. Crane, of the New York Continental Jewell Filtration Co., and Martin F. Newman, Assistant Manager of the Water Purifying Department, Wm. B. Scaife & Sons Co.

The committee presented its report to the Council on November 10, 1916, and it was received and ordered printed. The report was presented to the membership at the annual meeting in New York, December 5, 1916, and it was discussed at this meeting. The report and discussion are reported in full below.

The Report

To the Council of The American Society of Mechanical Engineers:

Your committee, appointed to make recommendations as to how to *rate the capacity of mechanical filters,* desires to submit the following report:

MUNICIPAL VS. INDUSTRIAL FIELD

2 The field of mechanical filtration may be arbitrarily yet definitely divided into two parts: One, the purification of drinking water or water for domestic supply, and the other the purification of water for other purposes, such as industrial uses.

MUNICIPAL PRACTICE SUBSTANTIALLY UNIFORM

3 On account of its importance and the large expenditure involved, especially in connection with municipal plants, much time and study have been given to all features of the filtration of water for domestic use. A large amount of data gathered through laboratory tests, and experience covering long periods in the practical operation of municipal plants, have brought into quite uniform adoption by all engineers engaged in such work the use of a rate of filtration of 2 gal. per min. per sq. ft. of filtering area for domestic supply.

DEPARTURES FROM NORMAL MUNICIPAL RATE PERMISSIBLE

4 While stating as a matter of information that such a rate is applicable in the great majority of such cases, your committee does not feel warranted in setting forth this rate as one to be adopted for all cases. As a matter of fact, the installation of a municipal filtration plant usually is done, and always should be done, under the advice and supervision of a competent filtration engineer engaged for the purpose, and the rate of filtration as well as other points of construction and operation should be left to his judgment, based upon the local conditions that may exist. For this reason, your

Received by the Council, November 10, 1916, and ordered printed. For presentation at the Annual Meeting, December 1916, of The American Society of Mechanical Engineers, 29 West 39th Street, New York.

committee feels that it is advisable and in accordance with the spirit and intent of your instructions to refer herein chiefly to the filtration of water for other than municipal purposes.

VARIOUS VIEWS CANVASSED

5 Your committee in considering this subject has sought information and assistance from many sources, and we desire herewith to express our appreciation of the many courtesies extended to us by those thus called upon for data or comment.

GRAVITY VS. PRESSURE FILTERS

6 It may be well here, in view of the misunderstanding that seems to exist to some extent, to make some reference to the two different types of mechanical filters known as the gravity type and the pressure type. With both types, purification is accomplished by passing the water through a filtering bed, which in practically all cases is sand, and the purification is dependent upon the property or power of the bed of sand to remove suspended impurities from the water passing through. This property is one inherent in the filter bed itself, and, while it will be affected by the rate at which the water passes, it is not altered by the incidental fact of the water being or not being under more than atmospheric pressure. While, with additional pressure available, more water can be forced through a pressure filter than a gravity filter of given size, there is no difference in the principles or methods employed that warrants a higher rate of filtration with such filters than is acceptable for open or gravity filters when similar results are to be obtained.

EXPERIENCE LEADING TO STANDARDIZATION

7 From the information gathered it was made apparent that experience has already brought about a substantial unanimity of opinion and practice on the part of all those who, as engineers, chemists or manufacturers, are brought into close contact with the field of mechanical filtration as to the limits within which permissible rates of filtration must fall. A very definite rate has become established in connection with municipal work, and indeed if there had been anything like the publicity in connection with filtration of water for other purposes that has obtained in connection with gravity filters such as are installed for municipal work, it is probable that there would have been no occasion for such investigation and report as this committee has been called upon to make.

TENDENCY TO OVER-RATING

8 While our investigation has made the above situation apparent, it has also developed the fact that there have been many filters installed in which the rate of filtration per unit of area is beyond, and sometimes far beyond, that at which good results can be expected or required. In some cases this has been due to the specifications under which the filters were installed, and in others, to what must be called an over-rating of the capacity of filters on the part of manufacturers. It is easily possible to force or pass through a filter of given dimensions much more water than it will properly filter, and in view of this it must be expected that there will be more or less yielding on the part of manufacturers placed under competitive conditions to the temptation to over-rate their filters.

NEED FOR DEFINITE, REASONABLE SPECIFICATIONS ON CAPACITY

9 This condition emphasizes the need and value of a pronouncement on this subject by some such body as The American Society of Mechanical Engineers which will serve for the information and guidance of those who, while having occasional need to specify or use mechanical filters, do not have opportunity to keep fully informed of conditions in that field. It is, therefore, hoped that this report and its recommendations will be of real value to engineers by placing before them information as to what is now the best opinion and practice, and thus enabling them to protect their own work and their clients' interests. To this end your committee most heartily and urgently recommends that when specifying filters there be included not merely the amount of water to be filtered per unit of time, but also specifications as to the rate of filtration per unit of area, or else the area or dimensions of the filter bed. Specifications thus written will insure fair competition and more satisfactory results.

IDENTITY IN GENERAL DESIGN

10 The same general design and the same principle of operation are followed by all the leading manufacturers of mechanical filters, the filtration being downward through a bed of sand superimposed upon layers of gravel, the filters being washed by a reverse flow of water. Competition in construction is, therefore, limited to the excellence of materials and workmanship, to the perfecting of details and to adaptations for convenience in accordance with good filtration engineering practice. While this affords abundant opportunity for conscientious care and requires familiarity with the history of filtration and thorough knowledge and observance of the results of experiments and tests, it does not allow any application of ingenuity to change fundamental requirements that are dependent upon natural laws.

UNNECESSARY TO STANDARDIZE CONSTRUCTION DETAILS

11 Your committee feels that it would be unwise, at least at this time, to attempt to standardize details of construction, there being a wide range in this field for individual preference or convenience, but there may well be established a standard in regard to the rate of filtration, since the object thereby sought is not mere uniformity but compliance with the limitations imposed by the laws of nature, so that the possible benefits of filtration will be actually and fully realized. It would thus seem to be self-evident, even if it were not fully established by experiment and experience, that the capacity of any filter is dependent upon and determined by two factors:

a The permissible rate per unit of area at which the water can be passed to insure the desired results.

b The effective area of the filter bed.

AGREEMENT AMONG LEADING FILTER MANUFACTURERS

12 It was made evident by the data gathered that there is a unity of opinion on the part of those best qualified to judge at what rate water may be passed per square foot of filter area to secure desired purification, and that there is a close agreement in the practice of all the leading filter manufacturers in rating the capacity of a filter.

FORM OF EXPRESSING CAPACITY

13 For convenience, we have expressed the rate of filtration in terms of gallons per square foot of superficial filter bed area per minute, thus combining units of quantity, area and time in a way to make easy the calculation of the amount of water any given filtering unit will properly handle or to estimate the area of filter bed surface that will be required for a given supply. The filtering area should be computed on the upper surface of the filter bed, as the latter lies during normal filtering operation, and no attention should be paid to a greater cross-sectional area such as is sometimes found in horizontal cylindrical filters.

CARE AS TO MAXIMUM DEMAND

14 In deciding upon the size of filters to be installed in any instance, very careful consideration should be given to the maximum flow that will be required at any time, and ample capacity provided. Where the demand is irregular, the maximum requirement is much greater than the average or minimum consumption, and either adequate storage for filtered water should be provided or the rated capacity of the filter made equal to the maximum demand. All filters are capable of passing more than their rated capacity, but beyond certain fairly narrow limits this is always at the expense of the quality of the filtered water, unless more than ordinary care is taken in efficiently coagulating the unfiltered water. As already intimated, the persistent use of moderately high rates above the normal and the occasional use of excessively high rates should be discouraged, if not prohibited.

DEPTH OF FILTER BED

15 While in a sense consideration of the filter bed may not be included within the instructions given your committee, we feel that some remarks in this connection will be of value, especially as there seems to be an opinion in some quarters that the use of a thicker filter bed or special methods or appliances for washing, or similar features, make higher rates of filtration permissible. In regard to such points, we would say, that while of course there is a minimum thickness of filter bed that must always be maintained for safety, better results do not follow increased depth. In fact, an excessive depth of sand bed is in some instances objectionable, as it may interfere with proper washing. We find that the minimum thickness of filter bed should be 27 in., of which at least 18 in. should be sand or similar fine material. A filter-bed thickness of 33 in., of which at least 24 in. is sand or similar fine material of suitable size and grade, is recommended.

INFLUENCE OF FILTER WASHING

16 While efficient washing of the filter bed must be provided for and while the use of special means or appliances, such as stirrers, air agitation or other means of breaking up the filter bed, may be of value in some cases as means of securing economy in time or of water consumed in washing the filter bed, the direct effect of such means is limited to that secured during the washing process and such effect has no influence one way or the other on the permissible rate of filtration, which is dependent upon and limited by properties inherent in the filter bed itself.

NORMAL FILTERING MATERIAL

17 The most desirable filter medium is a granular substance of a hard, non-porous, insoluble character, with grains substantially uniform in size and shape, the exact size and uniformity of the particles being open to some variation depending upon local conditions. If properly washed, such a filter bed will remain in efficient working condition for several years.

SPECIAL FILTERING MATERIAL

18 Bone charcoal or other porous material is sometimes of aid in the removal of iron, color, tastes or odors. But if they are used it must be recognized that growths of bacteria in the effluent are very likely to occur, although there is no evidence to indicate that such growths include disease-producing germs. These porous media may be used in single or double filtration, as noted in Pars. 20 to 23, inclusive.

RECOMMENDED RATE OF FILTRATION

19 The permissible rate of filtration in any instance depends upon the character of the water to be filtered and the purpose for which the water is used. If the water is for domestic purposes, whether the filters are installed in a municipal plant or otherwise, the rate of filtration should not exceed that which has been adopted for such service by universal consent of filtration engineers. We therefore recommend that:

a Whenever the water is to be used for domestic purposes or to secure full bacterial purification, the capacity shall be based upon a rate of filtration not to exceed 2 gal. per min. per sq. ft. of filtering area and a coagulant must be used.

b Where a lesser degree of purification is required, either because the water is not to be used for domestic consumption or because the water to be filtered is already sufficiently free from bacteria, or where the filtered water is to be effectively sterilized, a higher rate of filtration may be used, but not to exceed 3 gal. per sq. ft. per min.

DOUBLE FILTRATION IN SPECIAL CASES

20 Your committee finds that there is a limited use made of double filtration; that is, the water is passed through two filters placed in tandem. The consensus of opinion of those consulted and the recommendation of your committee is that when both filters are filled with the same medium this is not the best practice, but that better results will be obtained from the same filters operated in parallel, if they are properly constructed, owing to the slower rate of filtration.

21 Double or tandem filtration may, however, be used to advantage under some special circumstances, as, for instance, where the filter medium in the second filter is of a very close texture, so as to secure the very highest quality of filtered water by removing fine suspended matters that may pass through an ordinary filter bed.

22 Double filtration may also be of advantage where the use of a coagulant is not desired or where it is intended to remove iron, color, odor or taste. In such cases sand can be used in the first filter and bone charcoal or similar porous medium in the second. Such practice, however, should be limited to cases where an increase in the numbers of harmless water bacteria, such as frequently occurs in the effluent of a porous filter medium, is not objectionable.

23 If double filtration is employed, the rate of filtration should not exceed the rate of single filtration, unless warranted

by the result of experiments or upon the advice of a competent filtration engineer.

STERILIZATION

24 In earlier years it was frequently the custom to sterilize filter beds with steam, but it was found that the benefit of this treatment was temporary, and it frequently resulted in the growth of water bacteria within the filter. At present, sterilization is normally and preferably secured in the filtered water through the aid of liquid chlorine, hypochlorite of lime, or ultra-violet rays. When properly applied, such treatment will destroy all objectionable bacteria.

PREPARATORY TREATMENT

25 While this report deals essentially with filters themselves, it is proper to point out that mechanical filters, with the rapid rate of filtration employed, cannot be expected to accomplish the best obtainable results without the securing of proper coagulation; and if the raw water is very turbid, then preliminary sedimentation also must be considered.

26 In closing this report the committee desires to express its deep loss in the death on August 7, 1915, of J. C. W. Greth, Mem.Am.Soc.M.E., one of the original members, and also its appreciation of his aid in collecting data on the practical state of the art and of his judicially expressed opinion as to the basis of this report.

Respectfully submitted,

George W. Fuller, *Chairman*,
James C. Boyd,
Arthur M. Crane,
Philip N. Engel,
Martin F. Newman,
William Schwanhausser,
Committee on Filter Standardization.

DISCUSSION

Jos. W. Ellms.[1] The recommendations of the committee making this report are in agreement with the best modern practice in the design of mechanical filters. They have quite clearly indicated the maximum limits for safe rates of filtration and the minimum depths for the filtering medium. Their conclusions on these points are in accord with the writer's own experience.

In declining to commit themselves in regard to construction details, they are probably justified; yet it might have been well to have enunciated some of the general principles which experience has shown to be essential to the best design. The writer has reference more particularly to underdrain, strainer and waste-trough design. Probably no portions of a mechanical filter are more directly dependent upon proper coördination than are those whose principal functions relate to the cleansing of the filter bed. So far as these portions of the filter act as distributors of the influent water to the filter bed, and as outlets for the effluent from the bed, their importance is only of a secondary character.

It is of the utmost importance that the underdrain system of a filter bed shall effect as uniform a distribution of wash water as possible. Whether this is done largely through strainers of various types or through perforated pipes, or in conjunction with the coarse filtering material forming the bottom of the filter bed, is of small consequence, so long as it is actually accomplished. Moreover, a uniform and speedy withdrawal of the dirty wash water by means of properly disposed waste troughs is as essential as uniform distribution of the wash water when entering the filter bed. In other words, a mechanical filter which cannot be quickly and effectively cleansed is defective.

It is to be hoped that the indorsement of the committee's report by the Society will establish certain definite principles of filter design to which manufacturers will conform, and by which purchasers of filters may be guided in judging of the merits of any particular design that may be submitted to them.

George A. Johnson.—The report of the committee recommending certain standard procedures in filter practice shows clear evidence that the general proposition has been viewed from the numerous necessary angles and the tentative conclusions drawn from approved practice in filter design and operation. At best the preparation of such a report was a difficult task, for the reason that in water-filtration problems local conditions govern so very largely, and their individual peculiarities are so numerous and varied. This report will serve a valuable purpose in the development of standard practices where possible of application, and the committee is to be congratulated for the skill and conservatism displayed in its preparation.

Frederick Schreibman, in the first of a series of articles in *The Iron Age* on improving operating conditions in machine shops without buying new machines or erecting new buildings, proposes to adopt the following plan whenever an expansion of a plant is attempted: *a*, to adopt a new location of machines at present used; *b*, to change the location or enlarge certain doors, windows, stairways and elevators; *c*, to strengthen certain parts of the first floor, etc.

In the construction and insulation of refrigerators "built in" on board ship, difficulty has been encountered with the use of cork that had not been sufficiently pressed previous to baking. This cork was not as dense as it should have been, and was lacking in mechanical strength.

As to refrigerator doors, the idea seems to prevail that they should have beveled edges and that such edges make a very tight door. However, as soon as the moisture begins to have its effect, such a door cannot be tight any more. Further, if the hinges yield at all, as they are likely to do with such a heavy door, it will never be tight.

The way to make a tight refrigerator door is to have a plain surface come up against a plain surface with a flexible gasket between them, or two pairs of such surfaces with gaskets between them, making an air pocket between the two sills. If this arrangement is used the door can sag considerably without causing any serious binding or failure in tightness.

As regards estimating the capacity of the refrigerator machine required to take care of the given refrigerator, it is not sufficient to calculate on heat loss through the insulation of the refrigerator, as it is only a part of the total loss. The other losses are due to heat entering in warm goods, by the interchange of air through the opening of doors, and by leaks through defective insulation or defective doors; to lights, or to the heat of the bodies of workers; to any change of state occurring in the goods, such as freezing, fermenting, etc.—R. F. Massa in paper at the Annual Meeting of the Society of Naval Architects and Marine Engineers, November 1916.

ANNUAL MEETING DISCUSSIONS

Written Discussions of the Papers Presented at the Thirty-Seventh Annual Meeting of The American Society of Mechanical Engineers, New York, December 5 to 8, 1916

IN the preceding issue was given an outline of the Thirty-Seventh Annual Meeting of The American Society of Mechanical Engineers, held in New York, December 5 to 8, 1916, in which it was aimed to give a comprehensive and yet not over-long account of the whole meeting. It was only possible to include in this outline the briefest abstract of the written discussions, which were exceptionally full.

It was hoped to give full publication to these written discussions in this issue of The Journal, but here again space precludes giving more than one-half the discussions and the remainder will be given next month.

The discussions are printed substantially in full, and will be found to contain a large amount of valuable material supplementing the subject-matter of the papers. Following the discussions are given, in each case, the authors' closures, which refer also to the oral discussion abstracted last month.

THE TESTING OF HOUSE-HEATING BOILERS. L. P. BRECKENRIDGE AND D. B. PRENTICE

William Kent. The method of rating a house-heating boiler proposed by the authors seems to leave out a most important factor of such a rating, viz., the grate surface, or the amount of coal that should be burned per square foot of grate surface.

The authors say, "The capacity or commercial rating of a heating boiler has always been given in terms of the direct radiating surface which it would serve." The capacity of such a boiler thus defined, that is, the amount of radiating surface which it will serve, is an exceedingly variable quantity, depending chiefly upon the amount of coal that is burned under it per hour, which in turn depends on the size of the grate and the rate of combustion. A certain boiler with 1 sq. ft. of grate and say 20 sq. ft. of heating surface may supply 150, 300 or 450 sq. ft. of heating surface, depending on whether the coal is burned at the rate of 4, 8, or 12 lb. per sq. ft. per hour. It is evident then that no satisfactory rating of a house-heating boiler can be made that does not take into consideration the rate at which the coal is burned. I therefore would amend the authors' definition of a unit for stating the capacity of a heating boiler so as to make it read as follows:

The *foot of radiation* shall be $\frac{1}{4}$ lb. of steam per hour condensed at 212 deg. fahr. and discharged as water at 182 deg. (equivalent to 250 B.t.u. per hour) when the coal is burned at the rate of 4 lb. per sq. ft. of grate surface per hour.

I use the figure 250 instead of the authors' 242.6 because it has long been used by heating and ventilating engineers as a standard equivalent for an average square foot of radiation. A radiator generally discharges its return water at a temperature somewhat below the temperature of the steam, and the figure 250 is therefore more nearly equivalent to the actual conditions of condensing $\frac{1}{4}$ lb. of steam than is 242.6.

In 1909 the writer presented a paper on The Testing and Rating of House-Heating Boilers to the American Society of Heating and Ventilating Engineers, which is published in the Transactions of that society. Some of the points in that paper are pertinent to the discussion of the present paper.

S. B. Flagg and R. L. Beers. The writers have been engaged during the past two years in planning and carrying on an extended series of tests which the Bureau of Mines is conducting for one of the Government departments. The principal purpose of these tests has been to obtain information as to the relative value for domestic heating purposes of a large number of fuels used by this department, including a number of Canadian and foreign coals. At the same time a comparison is being made of steam and hot-water boilers.

The reasons given in the paper why it is important to have a satisfactory method of testing house-heating boilers are heartily indorsed. The writers would add to these reasons by pointing out that in many localities anthracite coal is practically unobtainable or can be used only at a much greater heating cost than for some other fuel. Consequently methods of firing and testing such boilers and the ratings established for them should take account of these other fuels, especially bituminous coal.

It is agreed that the lack of clearness as to the meaning of *a foot of radiation* is undesirable and should be corrected. In reporting results of tests of boilers of the hot-water type, the employment of a unit such as the paper describes would be especially desirable for comparison with steam-boiler tests.

In the development of plans for the tests which the Bureau is now conducting the following considerations governed:

The average residence-heating boiler operates during the most of the heating season at a load less than 40 per cent of its rating. Results were desired showing the comparative values of the fuels under average load conditions, and the tests were therefore run at approximately this load.

Conditions of attention were to be comparable to those in actual service so far as possible. For this reason with most fuels charges of relatively large size were fired so as to give a firing period ranging from 6 to 12 hours.

In the case of the steam boiler installed in a residence, neither the rate of delivery of steam nor that at which the condensation returns is uniform. The boiler output was therefore allowed to vary, but the valve controlling the delivery was so set that with automatic damper regulation an average load of approximately 40 per cent of rating was maintained. This corresponds with the authors' requirement in Par. 12*a*.

So far as possible the test data were mechanically recorded and some of the data so recorded by a second piece of equipment.

In order to reduce errors of starting and stopping the duration of the tests was made approximately 48 hours.

The authors concede that when the load is allowed to vary the conditions of house operation are reproduced, but they feel that under such circumstances it would be difficult to duplicate results. Tests conducted at the Bureau's experiment station do not justify such a conclusion, and the writers' opinion is that the real purpose of the test should be to learn what the boiler will do under operating conditions. If it be agreed that such is the purpose the effort should be to approximate the operating load. Observations taken at the time the Bureau's plans were being developed showed that the actual delivery of steam by a residence-heating boiler varies

through a considerable range, even in moderate winter weather, and is affected principally by the times and conditions of firing, and the character of the fuel.

It was the effort when the Bureau's tests were first started to employ a method of starting and closing tests similar to that proposed in Par. 17 of the paper. The duration of the full test was then and still is made approximately 48 hours, and at the end of the first 24 hours the fires were brought to a closing condition and readings taken. Experience with this method, particularly with anthracite coals, showed so great variations between the two 24-hour periods and also between different tests that it was abandoned for what was formerly known as the "standard" method of starting and closing. With the latter method of test the overall efficiencies are usually lower, but results can be more easily checked with 24-hour tests by this method than by 48-hour tests by the former method. The following results illustrate the variation:

Test	Coal	Method of Starting	Duration (hours)	Total Coal per sq. ft. Grate	Overall Efficiency %
761......	Anth. Egg.	First.	47.07	89.6	77.6
761 (a)...	"	"	24.28	51.8	80.0
761 (b)...	"	"	22.78	37.8	74.5
868......	"	Second	24.25	80.3	62.8
853	"	"	49.37	128.3	62.9

The proposed method of starting and stopping can probably be used with a fair degree of success with anthracite coal of stove or chestnut size, but the writers' experience with other sizes was anything but encouraging. The evaporative performances quoted by different manufacturers, nearly all of which are believed to be for anthracite coal, appear high, and it may be due to the effort to get results with a short test or to the use of a method of starting and stopping which does not give correctly the quantity of fuel actually consumed.

It is obvious that the proposed method of starting involves less work in both the conduct of the test and the analysis of fuel and refuse samples than does the other method wherein the test is started with a new fire and analysis is made of the material remaining on the grate at the close of the test. It was because of this difference that the effort was first made to start with a fire which has been burning for 3 or 4 hours, but the writers were not able to carry out the method successfully with anthracite, lignite and some of the sub-bituminous coals, and they are of the opinion that others would experience similar difficulty. A duration of test sufficient to show a total fuel consumption of 40 pounds per square foot of grate is, however, believed to be adequate if the so-called "standard" method is used.

The feeding of water to the boilers may be done as described in the paper or it may be done in another way if the output rather than input is measured. The latter course is followed in the Bureau's tests.

Connection may be made by a small line from a source of water under pressure to the return outlet of the boiler. In this line a small orifice may be placed and the pressure drop through the orifice read off of a manometer graduated to read in rate of flow or simply in pressure difference. The manometer shows at any time at what rate the water is being fed, and this feed can be adjusted to keep the boiler water level practically constant.

Measurement of output can readily be made in either of two ways. One way is to send the steam delivered by the boiler through a closed-type feedwater heater, the condensing water circulating in the coil, and measure the condensate. The other way, which would obviate the use of calorimeter readings in computing results, is to measure the quantity and rise in temperature of the condensing water, the condensate returning to the boiler. Selection of equipment for either method may be made from a wide variety, and nearly any desired degree of accuracy obtained in measuring the output.

ROY E. LYND. There are two points in this paper which I would like to discuss. The first is that the titles of the paper and of the proposed testing code both confine themselves to house-heating boilers, and the paper states that the class of boilers indicated by the authors under this heading includes only boilers designed to serve 2000 ft. of radiation or less. It seems that we make a mistake in thus limiting this code. The same boilers which we use in our houses are used very extensively to heat schools, churches, and other large buildings, and several makes of low-pressure cast-iron sectional boilers are designed to serve as much as 10,000 ft. of radiation. We would do well to eliminate the term *house-heating boilers* from the title, the paper and the code, and substitute therefor *low-pressure heating boilers;* and include all low-pressure heating boilers instead of those only which are designed to serve 2000 ft. of radiation or less. The larger boilers of this class are covered by section (9) of the code, which states that the test conditions should be as nearly as possible like the ordinary operating conditions for the boiler to be tested.

In the A.S.M.E. Boiler Code of 1914, boilers are divided into two classes.—Power Boilers, Section 1, and Boilers used exclusively for Low-Pressure Steam and Hot-Water Heating and Hot-Water Supply, Section 2. This division should be borne in mind in any new testing code. As the proposed testing code is essentially a code for evaporative tests, we are not concerned with boilers for hot-water heating and hot-water supply. It would seem therefore that the new code should cover all boilers used exclusively for low-pressure steam heating, and should be so entitled. The A.S.M.E. Boiler Code, in Section 2, does not limit low-pressure heating boilers to 2000 ft. or less, and we should not so restrict the testing code.

The second point is in regard to the definition given for a *foot of radiation.* The authors seem to think that the amount of steam condensed per foot of radiation enters more largely into ordinary heating calculations than the B.t.u. They have assumed a convenient average amount of steam per foot of radiation, and have then converted this into an awkward B.t.u. value. This, to my mind, is wrong. We figure practically everything in connection with heating installations in B.t.u.'s, and it is very rare that the question of the amount of steam involved is raised. I would suggest that the *foot of radiation* be defined as a transfer of heat equal to 250 B.t.u.'s per hour. This figure, and its reciprocal, 0.004, are both very convenient, and would be far preferable to the figures given by the authors.

It has been the writer's practice to test low-pressure boilers at atmospheric pressure, keeping a record of the steam temperature as indicated by a mercury thermometer placed in an oil well directly in the steam chamber in the top of the boiler. The pressures at which these boilers are operated are as a rule so nearly atmospheric, if the heating system is conservatively designed, that a test made at atmospheric pressure comes about as close to actual operating conditions as it can be got. The great advantage of the atmospheric pressure test is, of course, its simplicity, it being unnecessary to use the reducing valve, receiver, and bank of valves spoken of by the authors.

One of the functions performed by this system of pressure control suggested by the authors is in the determination of the time of starting and stopping the test. The test is started

by establishing normal running conditions with a pressure of, say, 5 lb. on the boiler. Then the fire is cleaned and thinned until the pressure drops to say, 3 lb., when the test is assumed to start. The same conditions are reproduced at the end of the test, the test being over when the pressure drops to the same 3 lb. This would all be out of the question with a test made at atmospheric pressure. The writer has used for some time a system which is very similar, and which gives practically the same accuracy, and which is applicable to tests made at atmospheric or any higher pressure. Normal running conditions are established before the test, and then the fire is cleaned and thinned just as outlined in the paper, but instead of depending on the pressure dropping to a certain starting pressure, the temperature of the flue gases is used as an index. When the temperature of the flue gases falls to a predetermined point, the test is assumed to be started, and at the close of the test the starting conditions are reproduced until the flue-gas temperature taken at the same point in the flue falls to the starting temperature. This method seems preferable, as the flue-gas temperature is more intimately connected with the condition of the fire than the steam pressure is, and at the same time it enables us to use the very much simpler atmospheric pressure conditions.

It has also been the writer's practice, for some time past, to keep accurate records of the draft in the flue, in the firebox, and in the ashpit, by means of differential draft gages. These data sometimes indicate differences in the draft conditions which may explain differences in test results.

Max Friedlander. Below is a description of a new method for the *continuous* determination of the heat balance of house-heating boilers. The principle of the method was suggested by Prof. H. Junkers, the originator of the Junkers calorimeter, and the method was tried out and applied by the writer in a series of actual tests on a steam-heating boiler in 1911 when he was his assistant at the Technical College of Aix-la-Chapelle, Germany.

The idea was to measure all items of a complete heat balance in a continuous way during operation, and for this purpose the boiler was suspended upon a sensitive balance, so the smallest amount of fuel burned off in the boiler could be weighed very exactly at shortest intervals, thus giving a continuous determination of the fuel consumption and the incoming heat. The arrangement is shown in Fig. 1.

The entire steam generated was condensed in a condenser and the condensed water carried back to the boiler. In this way the useful heat could be determined continuously by continuously measuring with a Poncelet vessel the quantity of cooling water used in the condenser and, with the thermometers, the increase in its temperature.

The flue gases were drawn out by a ventilator and carried through a flue-gas calorimeter, in which their entire *sensible heat* was determined by cooling them down to the room temperature by a water jacket, the quantity of cooling water being measured continuously with a Poncelet vessel, and its rise in temperature also being measured. The volume of the flue gases was recorded with a gas meter of 1500 liters capacity per revolution.

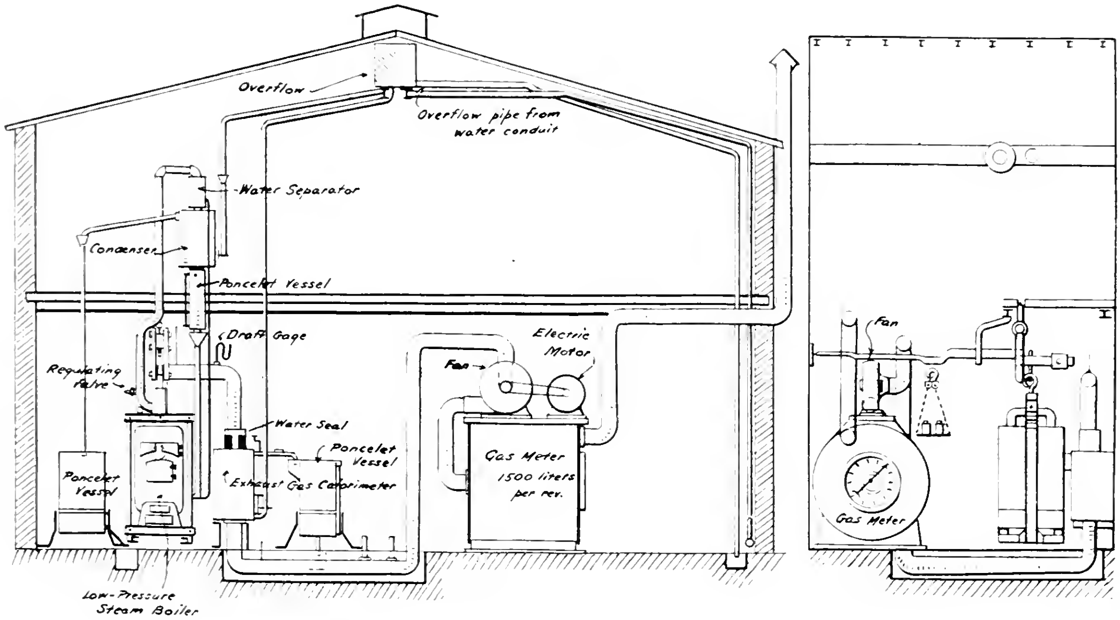

Fig. 1 Testing Low-Pressure Boilers at the Royal Technical High School, Aix-la-Chapelle, Germany

A quite novel feature was the continuous determination of the loss of heat due to incomplete combustion by a new calorimetric method in which the heat value of the flue gases was measured in a calorimeter fitted with a specially designed burner for which a patent is pending. This method for the calorimetry of flue gases has been developed by the writer in separate experiments and tried out in a great number of actual tests and applications on boilers and combustion engines, and it has been described in detail in a dissertation (not yet published), where all these experiments and tests are also reported. The arrangement for this is also shown in the illustration.

The heat loss due to incomplete combustion was very variable and, with the boiler mentioned, wavered between 8 per cent and 23 per cent of the incoming heat when the operation and combustion was normal, and increased to over 45 per cent when the boiler was operated with insufficient excess of air or otherwise in bad condition. In all cases, however, the heat value of the flue gases decreased continuously, or, in other words, the combustion improved steadily in the proportion

as the layer of coal was burning off, thus indicating that the boiler was working in the beginning like a gas producer.

Heat radiation and conduction was determined by temperature measurements of the outer surface of the boiler and its surroundings, and by use of individual coefficients of heat transfer.

CLOSURE BY PROFESSOR BRECKENRIDGE

L. P. Breckenridge. The authors appreciate the discussion and suggestions presented by the different members. It is evident that the time has arrived for adopting a plan for testing house-heating boilers. It is probable that the Power Test Committee will be able to use the suggestions made in the discussion when they come to give consideration to this paper.

At no place in the paper do the authors discuss a method of rating boilers. That is a matter for future consideration. We still believe that in spite of the convenience of 250 B.t.u., the reason already given in the paper is of sufficient weight to justify asking that the most careful consideration be given to the authors' proposed definition of a foot of radiation.

THE UTILIZATION OF WASTE HEAT FOR STEAM-GENERATING PURPOSES, ARTHUR D. PRATT

Warren B. Lewis. The extraction of waste heat from furnace gases has not always been successful, and the unfortunate examples have been heralded fully as much as the successful ones. Boiler economizers are the most widely known waste-heat extractors; and their success has been due, in no small measure, to a thorough understanding of the characteristics of the gases to be handled. The conditions surrounding steel furnaces have not been so thoroughly understood, nor the requirements of the furnace so well appreciated, so that the apparatus for recovering waste heat has not been standardized.

The following description of a plant using waste-heat boilers in which the transfer rate is low is cited to show what has been accomplished from a different reasoning point to that employed in the paper.

Admitting at the start that mechanical draft is practically a necessity, the regulation of draft takes place in the flue between the furnace and the boiler, or, to put it another way, a certain definite draft must be maintained at the end of the checkers. What happens beyond that point is of comparatively small importance.

The furnaces were fired with producer gas made from bituminous coal. The amount of coal consumed in a year was 8400 tons. The gases between the producers and the furnaces were analyzed, as were also the gases between the checkers and the stack; and a determination made of the weight of gas issuing from the stack. The temperature of the gases averaged 1050 deg. fahr., and the boilers were designed to abstract 550 deg. fahr.

The boilers chosen were of the Manning type, with tubes 20 ft. long; and draft was produced by means of a motor-driven steel-plate fan mounted on a platform at the top of the boilers. A rotatable steam-jet tube blower was installed, by means of which the tubes could be blown out as often as desired with a minimum of labor. The ground space occupied was small, and the protection necessary from the weather inexpensive. The boilers were equipped with automatic feed-water regulators.

The early calculations in connection with this installation showed that there should be an average output of 212 boiler hp. One year after the investigation was made the boilers were in operation, and the actual boiler horsepower developed was 227; the temperature of the flue gases was 418 deg. fahr. The total square feet of heating surface was 6600, and the transfer rate less than 2. The actual power required to drive the fan was about $2\frac{1}{2}$ per cent of the net return from the boilers.

The tests showed a comparatively high percentage of recovery, as indicated by the low temperature of the flue gases issuing from the fan.

In order to recover a high percentage of heat with a low transfer rate, a large amount of surface must be used; and it is simply a question of what that additional surface costs as compared with the cost of a high-pressure drop.

L. D. Ricketts[1]. The Cananea plant is the oldest one installed with the header type of flues for the distribution of the waste-heat gases to the boilers. In more modern smelters in the Southwest, Stirling boilers or ones of similar type but of much larger capacity are used. They are equipped with superheaters. Economizers have not been installed recently on account of their tending to become foul and to cut down the draft in the furnaces.

The new plant of the International Smelting Co., near Globe, Arizona, has three reverberatory furnaces, each 21 ft. wide by 120 ft. long, and seven waste-heat boilers of a capacity of 713 boiler hp. each, and they are supplied with superheaters which furnish 50 deg. of superheat to the steam, which is generated at a pressure of 195 lb.

We find it advantageous, however, to use three boilers to a furnace, and now that we have to increase the size of the plant and add an additional furnace, we contemplate installing three more boilers of this size so that we can do this in operating three furnaces and have one boiler as a spare.

It may be of interest in this connection to give some idea of the amount of power recovered at a plant like the one in question.

Each of the furnaces treat about 500 tons of solid charge per day, and with two furnaces running continuously the plant smelts about 30,000 tons of solid charge per month. The evaporation from and at 212 deg. in the oil-fired boilers in the power house is 16.46 lb. of water per pound of oil. The evaporation in the reverberatory furnaces is 7.32 lb. of water per lb. of oil. In other words, a pound of oil burned for smelting purposes in the reverberatory furnaces yielded on an average (for the first ten months of 1916 at the International Company's plant) 44.77 per cent. of the power such oil would yield if burned under its boilers. The gross oil consumed in smelting was 0.856 barrel per ton of solid charge, and of this 0.475 barrel was charged to smelting and the balance to steam generated.

B. N. Broido[2]. Waste heat is also very often used in Germany to superheat steam. In cases where for some reason superheaters cannot be installed in boilers, or in which circumstances require the superheater to be near the engine, independent superheaters are recommended. In such cases superheaters heated by waste gases are the ideal installation.

The writer has designed and installed a number of superheaters both large and small for waste heat. Fig. 2 shows such a superheater for 40,000 lb. of steam per hour, installed at the plant of the Coal Mining Co., Gelsenkirchener Berg-

[1] 42 Broadway, New York.

[2] 228a Rector Street, Perth Amboy, N. J.

werks Gesellschaft. The gases had an average temperature of about 1382 deg. fahr.

The moist steam enters the superheater at *A* in order to prevent rapid burning of the tubes at the point where the gases first come in contact with them. The steam flows through this portion of the superheater in the same direction as the gases, passes over to *B* and flows in the opposite direction, taking full advantage of counter-flow principle.

With a velocity of the flue gases of about 900 ft. per min., and a velocity of steam inside of the pipes of about 5000 ft. per min., the average heat transfer was 4.3 B.t.u. per sq. ft. per deg. fahr. temperature difference. The steam for this superheater was supplied by five waste-heat water-tube boilers, 300 hp. each, four of which were always in operation.

On account of its smaller heating surface the cost of this independent superheater was considerably smaller than it would be with each boiler provided with its own superheater.

Most of the superheaters have been installed for waste heat from coke ovens and open-hearth steel furnaces. Also copper furnaces and cement kilns often furnished waste heat for superheaters.

have been in accordance with early rather than modern waste-heat practice; that is, gas velocities comparable to those now used in open-hearth, cement-kiln and beehive coke-oven work have not been used. In view of the success of the application of this principle in these industries, and from a comparison of exit-gas temperatures from boilers set with smelting furnaces and temperatures from the modern design of waste-heat boiler, it would certainly appear that a trial installation at least of the modern design is warranted on the part of one of the copper campanies.

Mr. Lewis in his discussion gives some interesting figures on the performance of a boiler with low-temperature gases where, based on the transfer rate, the velocity must have been very low as compared to modern waste-heat-boiler velocity. He points out that for such low transfer rates the amount of surface to be furnished for a given capacity must be high. The boiler in question, presumably of 660 nominal rated horsepower, cooled approximately 48,000 lb. of gas per hour from 1050 to 418 deg. and developed 227 hp., or some 34 per cent of its normal rating. It is interesting to compare the heating surface of a modern waste-heat boiler to develop the same

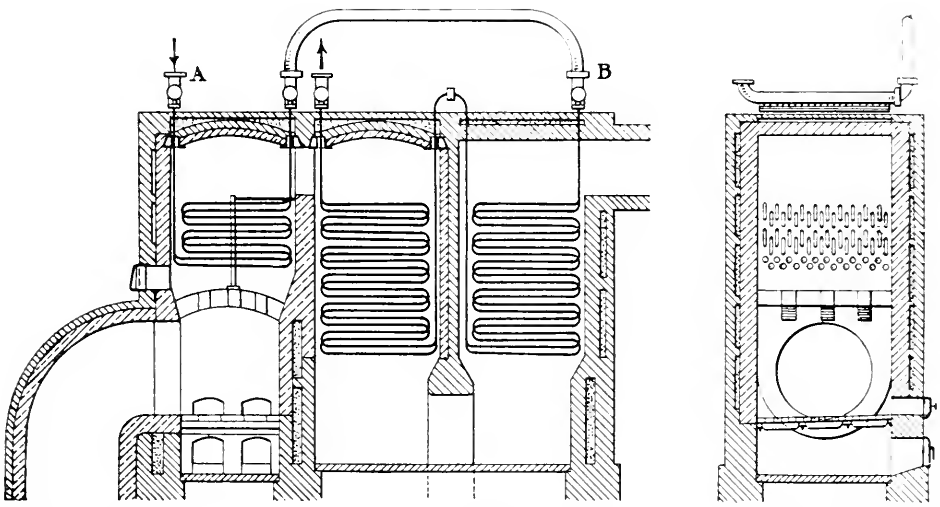

Fig. 2 Independent Superheater Utilizing Heat of Waste Gases. Capacity, 40,000 Lb. Steam per Hour

Mr. Pratt's Closure

Arthur D. Pratt. Mr. Christie raises the question as to whether the principles of high gas velocity could not be successfully applied in direct-fired work. This has been tried a number of times, and the absence of unqualified success has come rather from improper boiler design than from faulty principle.

It is of interest to note that there have recently been sold a number of direct-fired boilers in which the principle of high gas velocity along the lines of modern waste-heat practice is followed. These units are not as yet in operation, but in view of the knowledge gained in waste-heat work there is no reason why the installation should not be wholly successful. That this view is warranted is best indicated by the boilers described in the section of the paper on Utilizing Beehive Coke Oven Gases. Here with entering gas temperatures of 2100 to 2300 deg. fahr., temperatures which at least closely approach the direct-fired practice at ratings of 200 per cent and upward, exit temperatures of about 475 deg. are secured.

The operating figures of the International Smelting Co. given by Dr. Ricketts are of interest. With one exception, all of the boilers furnished with copper reverberatory furnaces

capacity with that described by Mr. Lewis. With such a boiler it is entirely possible to cool this weight of gas from 1050 to 418 deg. and thus develop 227 hp. (It is to be remembered that the temperature to which it is possible to cool a gas is to an extent governed by the pressure carried in the boiler.) The amount of heating surface necessary for such capacity, however, would be approximately 3500 sq. ft. as compared with 6600, and this heating surface would be operating at some 65 per cent of its normal rated capacity.

Mr. Lewis states that the power required to drive the fan was approximately $2\frac{1}{2}$ per cent of the net capacity of the boiler. With the gas velocity through the boiler corresponding to the transfer rate obtained, the draft loss through the boiler proper must have been very low, and it is possible that the duty of the fan consisted largely in furnishing draft at the checkers. If the ordinary draft of 1.4 in. was required at the checkers, with the furnace directly connected to a natural-draft stack, the height necessary for a gas temperature of 1050 deg. would be approximately 150 ft. With the boiler installed and the gases cooled to 418 deg., this height of stack will give at the boiler outlet about 0.75 in., which would not be sufficient for proper furnace operation.

As compared with $2\frac{1}{2}$ per cent of net power required for the fan with the boiler described, a motor-driven fan for the modern design of waste-heat boiler would require approximately 4.4 per cent of the gross output. A turbine-driven fan for the modern unit would require approximately 6.4 per cent of the gross output, but if the exhaust from the turbine could be used in a heater, a large part of this power could be returned to the system.

While, as Mr. Lewis states, the question involved is the cost of additional surface as compared with the cost of a high-pressure drop (for a net capacity), the foregoing comparison seems to be decidedly in favor of the modern design.

Mr. Broido's discussion, in which he refers to the utilizing of waste heat for superheating steam, brings out a point that was perhaps not sufficiently emphasized in the paper, namely, that by far the greater portion of modern waste-heat boilers installed have been equipped with integral superheaters. The high gas velocity has the same effect in increasing transfer rates in superheaters as in boilers, and the amount of superheat being obtained even with low-temperature gases is comparable to what would be secured from the same amount of superheating surface in direct-fired boilers.

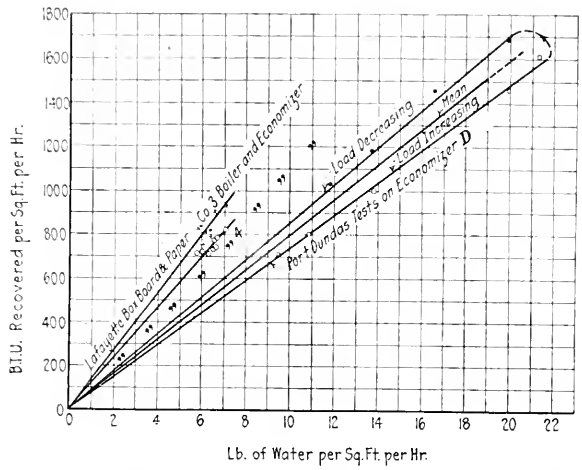

Fig. 3 Relation of Heat Recovery of an Economizer to Rate of Water Flow

Several installations have also been made of superheaters outside the boiler proper after the manner of separately fired superheaters. In one plant with which the writer is familiar such superheaters were set in the flue connecting open-hearth furnaces to waste-heat boilers. In these superheaters a transfer rate of approximately 6 B.t.u. was obtained.

In one or two other installations superheaters have been placed outside of the setting in the exit boiler flue. Such a location, however, would only be practicable with boilers where the gas velocities were such as would result in high exit-gas temperatures.

GRAPHIC METHODS OF ANALYSIS IN THE DESIGN AND OPERATION OF STEAM POWER PLANTS, R. J. S. PIGOTT

C. F. Dixon. We are building in Buffalo a station which will be equipped with three 20,000-kw. Curtis turbine generators and five 11,500-sq. ft. B. & W. boilers and Green economizers. We placed in operation on November 26 one turbo-generator and two boilers. Our operation is in conjunction with Niagara power, so that the steam plant is in operation now only about twelve to fourteen hours a day, and we are confronted with the problem of starting and stopping these large units from no load to full and reverse on very short notice. The starting is quite simple, as the underfeed stoker responds very rapidly to load demands. Our chief difficulty is in the loss of auxiliary steam during the starting period before the main unit is started. This is the only period I have ever found where electric-driven auxiliaries would show any value, and this period does not extend over 20 to 30 min., and would never occur in a 24-hour plant.

Stopping these large boiler units is the most difficult problem we have, especially with the high volatile coal used. We have found that banking with green coal is out of the question. We are able, however, to take our boilers out without loss of steam if we have 20 min. to burn down fires before load is withdrawn.

I cannot agree with Mr. Pigott's statement that the economizer has grown undesirable through the use of higher boiler pressures. With higher boiler pressures have also come higher boiler ratings, with their consequential higher flue temperatures, and the economizer can be made to pay for itself under these conditions. The construction, however, must be materially changed for the higher pressures.

F. A. Wardenburg. In this paper Willans input-output lines are ingeniously applied to the design of the power plant. In the paper two examples are worked out, where most exact information on each unit is plotted. It is not possible to secure such accurate data except from actual test on an operating plant, and in very few cases are these data available in making a design. There is no advantage in working out a design so minutely when the figures ordinarily obtainable are speculative. A great many things vital to the design of a power plant are not subject to exact analysis and must be left to the judgment of the designer; this being the case, it is straining a point to apply such exact analysis to the parts of the design for which figures of more-or-less doubtful value are available. Further, the proposed method does not take into account return on investment, which is one of the most important considerations in the design of a power plant. The designer can, by direct figuring, determine the necessary features of design more easily than by the use of the Willans input-output curves.

MR. PIGOTT'S CLOSURE

R. J. S. Pigott. Several who have discussed this paper seem to have mistaken entirely the source of the data on these curves. The method is practically without use if the data must be plotted from tests; in neither case were any test data available at the time the graphic curves were made up. They are made entirely from guarantees, and the data are no more exact than is usually the case in obtaining guarantees, except in that they are complete; but the use of the input-output line allows one to get the complete characteristics of a unit from two or three guaranteed points. This is especially true of such apparatus as boiler-feed pumps and fans.

The criticism that this method cannot be made to take care of financial features is not true; in one case in the paper I have done it, and it is just as easy to treat the investment costs in the same manner by the use of the double panel curve used by Mr. Stott when figuring total cost of power. If Mr. Wardenburg's statement about direct figuring being easier than the graphic method were true, there would be no necessity even for such things as load curves, because they can

always be figured from the log sheets. I do not believe that anybody who has made extensive use of graphics would agree with this.

With regard to Mr. Dixon's and Professor Greene's questions raised relative to the economizers, I would say that if the use of the steel-tube unit were adopted, most of my objections to the economizer in its present form would disappear; but in this paper I have been considering constructions as they are standard on the market at the present time. Certainly the reliability of the economizer would approach that of the boiler, if put into steel-tube form.

Mr. Reinicker's method is simply a short cut permitted in an operating station, by the presence of venturi meters. Naturally, advantage should be taken of the opportunity to elide some of the steps. I must repeat again that the paper is a mere indication of the application of the method. The variations in detail and in general are endless. To sum up, the use of input-output lines, both of individual apparatus and combinations of apparatus, is the easiest and safest way of getting information for all loads. Individual calculations for a single point at a time do not show the important changes taking place around cut-in points, and are not as likely to be accurate.

POWER-PLANT EFFICIENCY, VICTOR J. AZBE

Geo. H. Gibson. The author states that "it is difficult to reason out just what effect load variations have upon an economizer as a heat absorber." However, in a given installation, if the heat absorption at any one load be known, the heat recovery at other loads will be approximately in a direct proportion to the rate of water flow, as indicated by the chart of Fig. 3, which gives the results of three different tests with variable loads. From the Port Dundas test, it would appear that the heat recovery while the load is increasing is somewhat less than while the load is decreasing. This is due to heat storage in the large mass of water in the economizer. If the heat recovery of the economizer for a given steady load is known, however, it is only necessary to draw a straight line through this point and the point for zero load, in order to determine the heat recovery at every other load.

One of the graphs in the paper purports to show the relation between velocity of gas through the economizer and heat absorption per square foot per hour per degree difference of temperature. However, the coefficient of heat absorption varies with the temperature of the gases as well as with the velocity. The relations between rate of gas flow, temperature of gases and average coefficient of transmission are shown in the accompanying chart, Fig. 4, which I have compiled from tests upon a large number of commercial economizers in various conditions of actual service. The temperatures marked upon the graphs are the mean temperatures of the gases, that is, the temperature of the gases entering the economizer plus the temperature of the gases leaving the economizer, divided by two. The rate of gas flow is stated in pounds of gases per foot of pipe in a section per second, that is, if there are ten pipes in a section of the economizer and each pipe is 10 ft. long, there will be 100 ft. of pipe per section, and the total gas flow per second would be divided by 100 to obtain the quantity set off on the horizontal axis.

Ed. A. Uehling. Mr. Azbe's paper covers the whole steam-power plant, and he makes many valuable suggestions as to how the heat now wasted could be saved. I shall confine my specific remarks to the operation of the steam generators, in which at least 50 per cent of the preventable heat losses occur, especially in the type of plants to which Mr. Azbe most particularly refers.

To obtain highest efficiency from a boiler three things are necessary, these in the order of their importance being (1) efficient combustion of the fuel, (2) efficient absorption of the heat generated by combustion, and (3) efficient rate of driving.

The difficulty in maintaining boiler efficiency is that so many continually changing variables are involved in its operation that fixed adjustments are out of the question. To maintain maximum boiler efficiency the fireman must have before him the information necessary to enable him to make the required adjustments intelligently, as well as the facilities necessary to make them. The draft must be varied to burn the coal necessary to produce the steam required. The steam gage tells him when to increase or decrease his draft. The thickness of the fire must be adjusted to the draft, so that complete combustion takes place with the minimum excess of air. Unless some means are provided by which the fireman can tell whether the relation between the draft and thickness of fire is right, he cannot know with any degree of certainty

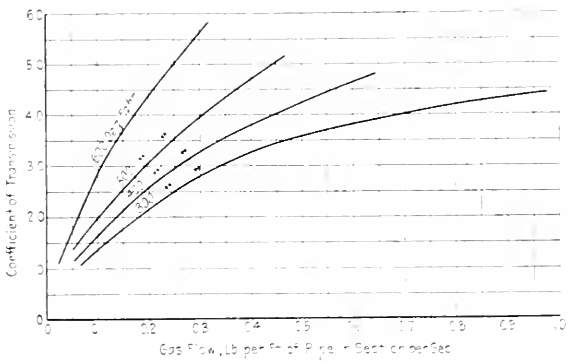

Fig. 4 Relations Between Rate of Gas Flow Through Economizers, Temperature of Gases, and Coefficient of Heat Transmission

whether his fire is too thick or too thin for economic combustion at the changed rate of driving. A CO_2 indicator at the boiler front tells him at a glance whether this adjustment is right, and what to do to make it so. Although the necessary draft adjustment to the steam demand and the fire adjustment to the combustion-efficiency demand can and must be made regardless of what the draft gage may indicate, it is none the less of great value to the fireman in making adjustments. He should have before him not only the boiler draft but also the furnace draft, the latter to indicate the condition of his fire bed and the former to indicate the rate of driving. Where positive information is required regarding the rate of driving, steam meters also must be installed.

The temperature of the escaping gas depends on four variables: (*a*) the condition of the boiler setting, including the baffling; (*b*) the condition of the heating surface; (*c*) the rate of driving, and (*d*) the percentage of CO_2 in the escaping gas. It is an index to absorption efficiency provided condition (*a*) is perfect and (*c*) and (*d*) are known. It is of no value to the fireman as a guide to combustion efficiency, because it depends on conditions beyond his control. A record of the temperature of the escaping gas considered by itself is also of questionable value to the operating engineer and may be entirely misleading, inasmuch as a low gas temperature may result from air infiltration as well as efficient absorption of heat by

the boiler, and high temperature may be due to a high rate of driving, dirty heating surface, or broken down baffling. To discriminate in the former case, we must know the percentage of CO_2, and to locate the cause of the latter we must know the boiler draft.

Although the flue gas temperature by itself is of no value to the operating engineer as a control, it becomes of some value when considered in combination with the boiler draft, and is of the utmost value in connection with the percentage of CO_2, because these two factors determine the heat loss up the chimney.

Boiler efficiency can be correctly ascertained only by accurately measuring the heat input and heat output. This, however, is neither feasible nor desirable under operating conditions. A system of efficiency control on the heat input-output basis was organized by Mr. Polakov for the Penn Central Heat & Power Co. in their Warrior Ridge plant, and described by him in a paper read before the Society in December 1913. This system of control approached scientific accuracy and gave excellent results, at least while under Mr. Polakov's able management, but it is too elaborate and cumbersome for general application, and to my knowledge has not been duplicated at any other plant.

Automatic coal weighers alone are of no value as a control for boiler operation, though they may be of some value as a check on the shippers' weights. Water meters are of more value because a more-or-less approximate estimate of the coal burned can be made at convenient intervals, perhaps monthly, and knowing the weight of water evaporated, a calculation of steam produced per pound of coal burned can be made and a rough idea of the combined efficiency of all the boilers obtained.

Diagnosis must precede the selection and application of the remedy, or a cure cannot be effected with any likelihood of success. Every boiler must be treated individually. The gas must be analyzed, temperatures must be measured and draft conditions observed continuously. To do this the necessary instruments must be supplied by the manager and intelligently used by the operating personnel, and if so used the highest efficiency which the conditions of the plant permit can be attained, and in no other way is it attainable. It has been accomplished many times by thorough combustion experts with the aid of an Orsat apparatus and a portable draft gage and pyrometer. This is very well and good. The trouble is the high efficiency established by the expert will not stay put. He has scarcely left the plant when it will begin to drop off, and in the course of a few weeks or months at most it will be down nearly, if not quite, to where he found it. High efficiency cannot be continuously maintained without instruments that will guide the fireman as to what to do, and will indicate properly the effect of what he did, and will autographically record the performance of both fireman and boiler as a control for the operating engineer.

Autographic records to be of the greatest benefit must be regularly and thoughtfully scrutinized and co-related, and the information they contain must be promptly acted upon, whether to bestow a praise, administer a rebuke, or correct a shortcoming in the operator or plant. The moral effect of the autographic record is very great if wisely used. Scientific apparatus cannot serve their purpose unless they are kept in continuous operating condition. They will not prove a paying investment if they are operated perfunctorily. They should receive the same regular and conscientious attention that must be given to the machines and apparatus which are vital to the operation of the plant.

MR. AZBE'S CLOSURE

Victor J. Azbe. In connection with Mr. Pigott's opinion in regard to maximum CO_2 desired, I wish to say that this is altogether a matter of type installation. With many installations it is not desired to go over 10 per cent; with others again 16 per cent and 17 per cent can be obtained without serious losses due to incomplete combustion. The most important factors in this problem are proper facilities for gas mixing and proper air distribution over the grate. We also must not forget that on one hand at high CO_2 percentages, CO might not be the only combustible gas escaping, and on the other hand that a given percentage of CO at high CO_2 percentages represents a great deal smaller loss than with the low CO_2.

Supplementing Messrs. Harrington and Polakov's excellent statements, I wish to say that while the manager is the one who is mostly responsible for the present condition, nevertheless the operating engineer shares also the blame to a very great extent, and the chief reason for the bad condition is that efficiency in power plants is taken, generally, too lightly, and this even by a great many professional men who really should be the leaders in agitation for better conditions.

I do not agree with Mr. Hunter's statement on CO_2 recorders, for the reason that I have had five CO_2 recorders of three different types in operation for two years, obtaining with them the most satisfactory results in our two St. Louis Anheuser-Busch plants. One man—not a college graduate—takes care of, changes charts and keeps in constant proper operation eighty different instruments, such as CO_2 recorders, recording pyrometers, steam-flow meters, venturi and other water-flow meters, etc., and in addition finds time to help with testing work. Where CO_2 recorders or similar instruments are not successful, it is generally due to not taking time to learn their principles of operation, and to improper installation.

Fig. 6 of my paper was not drawn to show exactly the economizer heat transmission, but rather the approximate relation between heat flow and draft loss, and represents conditions in the economizer at about 300 deg. fahr. mean temperature difference. Mr. Gibson mentions that the rate of heat transmission varies with the temperature. I wish to say that it varies rather with the mass of the gas and the velocity, both of which are, of course, dependent upon the temperature. Heat transmission in economizers with a given gas velocity will also vary, due to the influence of such factors as cleanliness of outside and inside heating surface, water velocity, and distribution of gas over the heating surface.

With Mr. Gould's opinion that I overlooked the most important point, "the character and quantity of fuel used," I do not agree, for the reason that while the quality and cost of coal are prime factors in planning efficiency methods and efficient equipment, they are not necessarily essential factors, so far as my paper is concerned. Preventable power plant losses are general over the whole country and where high as well as low-grade coal is burned, and if it pays to prevent the losses in small plants burning low-grade and at the same time cheap coal, it certainly should pay in larger plants or with higher-grade and more costly coal.

THE FLOW OF AIR AND STEAM THROUGH ORIFICES, HERBERT B. REYNOLDS

Sanford A. Moss. The author has executed some difficult experimental work in a very creditable manner. The coefficients for venturi meters at high densities are valuable pieces of contributory evidence to the general principle that an orifice or venturi coefficient is nearly unity.

The coefficient which Mr. Reynolds gives for the Taylor pitot tube is the product of the ratio of average to central velocity and of the static-hole constant of the Taylor tube, which is not unity.

Some remarks may be made regarding the formulæ used. The venturi formula given is the correct general formula both for the venturi and the plate orifice. It should never be used for computation work, however, as simplified formulæ give equal accuracy with vastly less computation.

For the case of Mr. Reynolds' venturis the differentials are exceedingly small, and the proper formula for cubic feet of standard air at 32 deg. is

$$\frac{491.5 \times 677.5\, d^2 \sqrt{P_2 (P_1 - P_2) / T_1}}{519.5 \times \sqrt{[1 - (A_2 / A_1)^2]}}$$

For the case of the table given on Page 29, this becomes

$$286.1 \sqrt{[P_2 (P_1 - P_2) / T_1]}$$

The following table gives a comparison. There is a constant difference of a fraction of a per cent. due to difference of fundamental constants.

From table on P. 29	From above formula
8.4	8.69
10.9	11.09
13.9	14.05
17.7	17.95
21.6	21.82
25.5	25.66
29.2	29.44
33.0	33.38
38.0	38.19
42.6	42.91
46.6	46.95

The formula used by Mr. Reynolds for the thin-plate orifice is theoretically correct only for pressure ratios greater than 0.52. For less pressure ratios, the flow is dependent on the initial pressure only. I understand that Mr. Reynolds has made his computations on this basis. However, Mr. Reynolds' actual results for small pressure ratios show that the flow does vary with the final pressure. This means that the coefficient of a thin-plate orifice varies with the pressures. The exact variation is given for the first time by Mr. Reynolds and he gives a very interesting empirical law, taking account of both the theoretical and the coefficient variation and giving the net flow.

The conclusion which I think should be drawn from the data presented is that the venturi meter is much preferable to the thin-plate orifice for the following reasons:

The venturi coefficient is well established by much previous data and by Mr. Reynolds himself, as nearly unity, while the coefficient of the thin-plate orifice is variable and the net flow is a complication of this factor and the theoretical flow. Mr. Reynolds' empirical formula is very ingenious, but it would have to be established for many other cases before it would be proper to use in general.

The corner of the thin-plate orifice has an important influence and even Mr. Reynolds used two different forms,—square and with 1/16-in. radius. I believe a venturi with a well-rounded approach and some length of parallel portion can be more easily made and duplicated than a true thin-plate orifice.

Mr. Reynolds also mentions, in the steam case, an uncertainty regarding point of measurement of pressure.

He complicates the venturi case by use of the full theoretical formula, whereas much simpler and equally accurate formulæ are available. He uses a rather large venturi throat, giving small differentials which are comparatively hard to measure. One of the great advantages of the venturi is the fact that large differentials can be used by proper selection of the throat diameter.

Hence I feel that Mr. Reynolds' paper gives valuable evidence showing that the venturi meter should not be displaced by the thin-plate orifice for the case of large pressures.

MR. REYNOLDS' CLOSURE

Herbert B. Reynolds. In regard to the relative merits of the venturi tube and the thin-plate orifice for measuring compressed air and steam, I wish to say that the venturi tube considered from the theoretical point of view is a more desirable instrument. However, when the cost and other practical considerations are taken into account, the thin-plate orifice has a great many advantages over the venturi tube, as is pointed out by Mr. Pigott.

In reply to Mr. Thurston's question as to the use of venturi tubes in parallel, I have no doubt that the apparent difference of pressure noticed by him when some of the tubes are shut off is due to the pulsating pressure, as explained by Mr. Connet.

The method of measuring the air described by Mr. Connet is probably as accurate as the method used in these tests. However, I think that the gasometer method is freer from uncertainties than any other method, as it is a direct measure of the actual volume of air.

Referring to Mr. Christie's interesting remarks about the close agreement of the coefficient of the Taylor pitot tube when used in a 10-in. pipe with the coefficient which I found for a 2-in. pipe, I find that, by referring to my original curves—which are easier to interpolate—the coefficients are about 0.78 for both the 2-in. and the $1\frac{1}{2}$-in. pipes.

I think that everyone will agree with me that the pinhole type of pitot tube is much to be preferred to the Taylor tube, as the coefficient of the pinhole type can be considered unity for all practical purposes if a traverse is made in the pipe or duct. The data for the Taylor tube were obtained in this case because it was desirable to calibrate this form of tube in connection with some other work.

I do not agree with Dr. Moss when he says that the formulæ which I have used should never be used for computations. One object of these experiments was to compare the actual performance with the theoretical performance, and thus I do not think that short-cut methods should be used on the theoretical side in order to save work any more than they should be used in determining the actual performance, namely, in the actual measurement of the air. A great deal of work and expense could have been saved if some simpler method had been used in measuring the air. However, the uncertainties would have been increased. On the other hand, a simpler formula might have been used in computing the theoretical flow, and giving the same degree of accuracy as pointed out by Dr. Moss, but at the same time involving uncertainties. Therefore I think in this case, with the object of the computations in view, the unquestionable correct theoretical formula should be used in comparing the theoretical flow with the actual flow.

I have made the above remarks about the approximate formula granting that it gives practically the same results as the theoretical formula. However, in investigating the formula as given by Dr. Moss, which becomes

$$Q = 286.1 \sqrt{P_2 (P_1 - P_2) / T_1}$$

for the 2×0.666-in. venturi tube, I find that for the lower pressure ratios it gives results which are quite far from the correct results. For example, the percentage of error varies from 0.64 per cent when the pressure ratio is 0.99892, to 34.62 per cent when the pressure ratio is 0.5821.

Dr. Moss states that the equation which I have used for the

orifice is theoretically correct only when the ratio of pressures is greater than 0.527. If used correctly this equation is theoretically correct for any ratio of pressure. However, when the ratio of pressures is less than 0.527, the value $0.527P_1$ should be substituted for P_2 in the formula. This was done whenever the ratio of pressures was less than 0.527.

Dr. Moss says that the size of the venturi throats which I have used resulted in very small differentials which are very hard to measure. Expressed in pounds per square inch, these differentials appear to be very small. However, it should be kept in mind that these pressure differences were measured in inches of water, which resulted in readings of considerable magnitude in most of the tests. In fact, in some of the tests the differentials were so large that it was necessary to use mercury in the manometer in place of water.

SPONTANEOUS IGNITION STUDIED BY MEANS OF PHOTOGRAPHIC PLATES, FREDERICK J. HOXIE

Milton F. Jones[1]. The subject of the early stages of oxidation of inflammable substances which, should the reaction continue, may terminate in spontaneous ignition, is a matter of importance regarding which very little is known.

If the author's assumption that the effect upon the photographic plate is due entirely to liberated hydrogen peroxide, is correct, then we have perhaps the first tangible evidence of the beginning of the oxidation process, in a form which would allow comparisons to be made.

That the density of the photographic image does not harmonize with the iodine number of the oil, is not remarkable. The iodine number of an oil is usually employed as a means of identification. It is based upon the capacity of the oil in question to combine with one of the halogens, that is, iodine. It is doubtful, however, whether we have the right to assume that the oil will combine with an equivalent amount of oxygen. Chlorine unites directly with some elements with which it is difficult for oxygen to unite.

Because the drying oils have as a rule the higher iodine numbers, and are prone to spontaneous ignitionn, it has been suggested that the iodine number might prove a guide in determining the tendency of an oil in this direction. Boiled linseed oil possesses greater drying properties than raw oil, and is usually considered more hazardous, yet it seems to have been conclusively demonstrated that it has the lower iodine number. The ordinary red oil which is a crude oleic acid obtained from tallow, an animal oil, is probably as hazardous as regards spontaneous ignition as linseed oil. Cottonseed oil is not considered a drying oil.

The statement of the author that all charcoal is not alike will hardly be questioned; it is one of the most perplexing factors in the investigation of charcoal fires. He finds that the density of the photographic image corresponds with the activity of the sample of charcoal, which is interesting. The conditions as to charcoal are different from those of oil. In the latter case, having determined that an oil is hazardous, it can be safeguarded more or less. With the charcoal, however, although many samples may show an inactive condition, one active piece favorably located in a pile may under certain conditions determine the destruction of the mass.

As the author states, the results are only a beginning, and subsequent research will determine the value of the process, whether of scientific interest only, or whether applicable to industrial or fire-prevention uses.

STANDARDIZATION OF MACHINE TOOLS, CARL G. BARTH

Fred A. Parsons. Regarding standardized progressions for speeds and feeds and standardized power, the paper presents what is without doubt the ideal condition, but in application the following points should be borne in mind:

1 At present a very small percentage of machine tools goes to factories where the management would appreciate the refinements in feed and speed ratios suggested. Indeed, the jobbing shop could never get together with the manufacturing plant on the question, since the former requires a wide range of speeds with large ratios and the latter a small range of speeds and feeds with small ratios.

2 Present machine-tool feeds and speeds are very largely the outgrowth of the above conditions, though there are no doubt many instances, as the author mentions, where no particular attention has been paid to anything except getting the high and low speeds required.

3 Present milling practice seems to require of general-purpose machines, such as the plain knee-and-column type, about the same number of feeds as of speeds, but a total ratio of about 24 to 1 for the speeds as against about 48 to 1 for the feeds. Unless present practice is wrong, this would require two different progression ratios.

4 Some designs permit considerable economies to be effected in space and parts required by attempting only a fairly close approximation of the perfect geometrical progression. An instance may be considered of obtaining nine speed variations with nine gears on three shafts, the gears on first and last shafts being sliding gears and on the intermediate being laterally stationary. In this case it is not possible to reach any perfect geometrical progression exactly, if the high and low speeds are even fairly far apart, but a close approximation can be obtained.

5 Considering that by practically any method of drive the variation from normal speed at no load and at full load will be up to 5 per cent, is it warrantable to add cost to a machine tool to come closer than a few per cent above or below a given geometrical progression?

6 Mr. Barth has stated in his paper, that the standardization of speed ratios should be accompanied by a standardization of power for machines of a given type and size. Such a standardization must be considered from the standpoint of the user. At present the users seem to demand two power capacities of any given range, one light and one heavy, and it is hard to see how this could be avoided, as otherwise some will be purchasing power capacity they do not need, though they require the range, and in the other extreme the reverse would be true.

7 It seems unquestionable that a few years more will see the development and general application of a machine-tool drive for both feed and speed in which the speed variations can be represented by a smooth curve from minimum to maximum. Such a drive is typified at the present time by the variable-speed motor; the objections are that it is expensive to install and cumbersome. Such a drive will not of course apply to lathe feeds for screw cutting, or milling-machine feeds for spirals.

Regarding the standardization of details such as T-slots, taper shanks, etc., which Mr. Barth mentions, there are not the difficulties which enter into standardization of speeds and power. The cases are quite different, inasmuch as if a T-bolt, for instance ¾ in. in diameter, is being used in an appropriate place, there must certainly be only one correct depth

of slot, considering strength for any given material, the same as there is one best size for the square and thickness of bolt head.

H. M. Norris. That some machine-tool builders are learning to appreciate the value of a smaller speed variation is attested by the fact that fifteen years ago no radial drill was provided with more than eight changes, while now they may be obtained with 20, 24 and 30. The speeds of most of these later tools are intended to be in geometrical progression, but I am of the opinion that a geometrical series is not the best for a drilling machine.

The ratio of progression most favored by Mr. Barth appears in the first column of Table 1. The second column gives the corresponding number of revolutions per minute, and the third the diameters of drills which this series would drive at a cutting speed of 80 feet per minute. To my mind this is not as efficacious a series as that obtained from a ratio giving both desired extremes, columns 4, 5 and 6. Here we have fifteen speeds for drills from 5/8 to 4½ inches in diameter, while under the former gradation there are but twelve.

But why use either? Instead of deciding upon a series and then seeing what drills it will drive at a certain cutting speed, is it not better to decide first upon the drill diameters and then try to obtain the exact speed for each, regardless of the ratio of advance? Suppose, for example, we set down, as in column 7, the diameters of drills we would like a machine to drive at a cutting speed of 80 feet per minute. It is an easy matter to ascertain at what number of revolutions per minute each should run, column 8. Here each *harmonic* group of speeds may be obtained from a five-change speed box or a 2-to-1 motor, while back gears made in the ratio of 1 to 1, 1 to 2, 1 to 4, 1 to 8, etc., will give as many successive *geometric* groups as desired.

Mr. Barth states in his paper that "It is by this time universally accepted by those who have a right to an opinion in this matter that the available speeds of a machine should be in a geometrical progression," and that "a discussion of this will not be undertaken by him unless provoked by some one else." It is not my purpose to provoke an argument, but I would like to learn if I am in error in thinking that my series is the best of the three.

TABLE I COMPARISON OF BARTH, NORRIS, AND USUAL METHODS OF CALCULATING DRILL RATIOS

Barth			Usual Method			Norris		
Ratio	R.P.M.	Diam. In.	Ratio	R.P.M.	Diam. In.	Diam. In.	R.P.M.	Ratio
1.000	43.3	7.09	1.000	67.9	4.50	4½	67.9	1.000

MR. BARTH'S CLOSURE

Carl G. Barth. While I am rather disappointed at the fewness of the discussions of my paper, the, on the whole, very favorable discussion by an engineer who has given so much independent attention to the subject as Mr. De Leeuw, is compensation enough for my having taken the trouble to prepare it. Regarding Mr. De Leeuw's comment that certain machines, as, for instance, large boring mills, would be better provided with two *bunches* of speeds, I agree with him fully; but will insist that each bunch should conform to the principles advocated by me. I also agree with him that more experiments with cutting tools should be made, and am pleased to inform him that more is known about the art of cutting metals with planer tools, milling cutters and drills than has as yet been published. For fully ten years I have thus had a set of slide rules covering certain milling cutters on the one hand, and gear cutters on the other hand, which have been of substantial assistance to me in my efforts to improve shop practices; and if I live long enough, I shall fully disclose their theory, construction, and application, together with much else relating to the art of cutting metals. Regarding Mr. Norris' discussion, it discloses such a fundamental lack of grasp of the whole matter considered, that I would be inclined not to waste any words upon it, beyond stating that it proves that he belongs to the other class I had in mind when I referred to "those who have a right to an opinion in this matter." However, being a great admirer of the many excellent features of the line of radial drill presses he has developed during a term of years, I am glad to point out that his mistake consists in neglecting to take account of the fact that the proper cutting speed of a drill—just as much as of a lathe tool and a milling cutter, etc.—varies with the diameter of the drill, the feed used, and the hardness of the material drilled; and that there is an exceedingly small increment between all the drills used in nearly every shop. Hence, theoretically, to meet every combination of these variables between a maximum and a minimum, infinitesimal increments would be required, in the absence of the possibility of obtaining which, *equal-percentage* increments become our only rational practical approximation; and that is, in a nutshell, all the reason and argument there is behind a geometrical progression of speeds, and it is all that is needed. Regarding Mr. Parsons' discussion, I fully agree with him that at present but a small percentage of machine tools goes to the factories where the management would appreciate the refinements of the feed and speed ratios suggested by me. However, it has been my business for a number of years to help managements to such appreciation, and I think the machine-tool builders should again help *me* do it. The field I can personally cover is exceedingly limited, whereas, theirs is unlimited. What he says about the relation of feeds and speeds of general-purpose milling machines is not clear to me, so I cannot comment upon it. I never expected all attempts at a geometrical progression of speeds to turn out even a practical perfection, but, I have fully demonstrated in my paper that there is no inherent difficulty in doing better in numerous instances than what has been done. I have said nothing in my paper that excludes any number of sub-standards of machine tools, as regards power. Thus, I fully believe that there might to advantage be both a heavy and a light standard of any work capacity (as opposed to chip-producing capacity) of several of the more common types of machine tools. For reasons that I prefer not to reduce to writing at the present time, while much misunderstanding still exists regarding my work as a scientific-management expert, I do not favor any kind

of continuous speed or feed variator for the mere sake of getting the closest possible speed adjustment (which nobody can hope to know closer than a rather uncertain percentage anyway, for any set of practical conditions), though under certain conditions I strongly advocate adjustable-speed motor drives, because of the quickness with which they enable speed changes to be effected.

ACCURATE APPRAISALS BY SHORT METHODS, J. G. MORSE

CHAS. W. MCKAY[1]. The reproduction cost of the property, tangible and intangible, the present or depreciated value of the property, the cost of producing and marketing the plant output, and the capacity of the plant, are all factors which should be carefully considered in attempting to evaluate an industrial property. Of these elements reproduction cost and present value, if not the most important, are at least worthy of careful consideration, and in the following paragraphs is briefly outlined a method of manufacturing-plant appraisement patterned after current practice in public-utility valuation work. The grand summary of such an appraisal would take somewhat the following form:

GRAND SUMMARY OF MANUFACTURING-PLANT APPRAISAL

	Reproduction Cost.	Present Value.
Direct Construction Costs:		
Land	....	(Same)
Buildings	....	....
Machine Tools (lathes, boring mills, etc.)	....	....
Auxiliary Equipment (chucks, etc.)	....	....

TOTAL NON-PHYSICAL ASSETS	....	....
GRAND TOTAL	....	....

Inventoriable Property. As to the inventory and appraisement of the strictly physical property, an appraisal made by a consulting engineer should be equally well adapted to serve for tax adjustment, insurance or accounting purposes or as a basis for the determination of fair value in the event of the sale or reorganization of the property under consideration. The inventory should be accurate, within reason, and should be based upon sound engineering and economic principles, so that it can successfully withstand the scrutiny to which it is almost certain to be subjected if presented before the courts.

Mr. Morse's plan is a little too broad to meet the requirements just outlined. He is merely satisfying his clients, or his employers, as to the physical value of the risks they are undertaking. They have sufficient confidence in him to warrant their acceptance of such short-cut methods as he may see fit to employ, knowing full well that he will be able to substantiate his valuation in the event of a call for claim adjustments. Nevertheless, it is very probable that the Factory Mutual Companies, or any other insurance organization, would be somewhat loth to accept valuations made by outside engineers based upon these rather broad-gage methods. In any event, it is probable that an engineer in submitting such an appraisal would experience considerable difficulty in "getting by" with the courts, in the event of a lawsuit over the value of a manufacturing property, or in using it as a basis for capitalization.

In a manufacturing-plant appraisement, the inventory should be made in sufficient detail to facilitate its ready analysis by opposing experts, in the event of legal action, and should be so arranged as to render the various elements of plant segregable for accounting or insurance purposes.

The attitude of the courts has been unfavorable toward real-estate appraisements made by consulting engineers, and, to be on the safe side, it is usually best in the long run to have land appraised by a real-estate broker of unquestionable standing and the buildings preferably by the architect under whose supervision they were erected. The auxiliary building equipment, however, such as elevators, piping and wiring, should, so far as possible, be considered as a part of the building rather than as a part of the machine equipment, as suggested by the author. Of course, exceptions may have to be made, as in the case of special wiring for motor-driven machinery.

As to the preparation of the unit costs of the inventoriable property, it is better for all purposes, with the possible exception of insurance appraisals, to carefully investigate them for a period of a year or two preceding the appraisal, and if those prevalent at the appraisal date seem to be abnormal, to use average prices.

Omissions and Contingencies. No matter how carefully an inventory may be made, there is always the probability that items, perhaps individually of small value, but which when taken collectively may amount to an appreciable sum, will be entirely omitted. In public-utility work, the usual allowance to compensate for such omissions, and one which has had the sanction of the courts, is two per cent of the reproduction cost of the inventoriable property.

The word "contingencies" as used in appraisal work may be defined as the monetary allowance which may be added to the appraisal of the inventoriable property to compensate for such unforeseeable contingencies as may arise in the construction of the property and which cannot be taken account of in the preparation of the unit costs. In public-utility appraisal practice it is usual to add an allowance of about two per cent of the reproduction cost of the inventoriable property. Similar conditions are encountered in manufacturing-plant appraisal work, and there is no reason why a specific allowance should not be made for omissions and contingencies.

Purchasing Expense During Construction is a very appreciable item, involving, as it does, the securing of competitive bids and possibly visits to the manufacturers' plants to inspect machinery. This may be cared for on a percentage basis, the allowance depending largely upon the nature of the equipment involved.

Tools and Tool Expense During Construction. This item includes not only the original cost of the tools, but also the cost of maintaining them during the construction period. In public-utility work, an allowance of 2 per cent of the repro-

[1] McMeen & Miller, 1454 Monadnock Block, Chicago, Ill.

duction cost of the inventoriable property is not unusual for this item.

General and Legal Expense During Construction. This item includes the general expense of the executive organization during the construction period, the cost of temporary offices for the bookkeepers, timekeepers, paymasters, etc., and the cost of legal counsel for incorporating the company. In manufacturing-plant-appraisal work a suitable allowance for this item, based on the reproduction cost of the inventoriable property and depending upon the nature of the property involved, will probably not exceed two per cent.

Engineering and General Supervision During Construction. Plans have to be prepared for the general layout of the buildings and transportation facilities, as well as for the distribution of the machinery in the buildings themselves, and in many plants it is customary to retain an engineer throughout the entire construction period to supervise the erection of the plant and the installation of the equipment. The usual allowance for this item varies from 5 to 9 per cent of the reproduction cost, depending upon the nature of the property involved.

Taxes and Insurance During Construction are unquestionably capital expenses, and should be included in the determination of the total reproduction cost of a manufacturing property. An adequate estimate may be made by ascertaining the insurance and tax rates prevalent at the time of the appraisal.

Interest During Construction. Up to the time the plant starts production, this item is just as real a part of the total investment in the property as is the cost of the inventoriable plant. For all practical purposes, interest may be computed with sufficient accuracy by ascertaining the interest rate prevalent at the date of appraisal and applying one-half of this rate to the total physical costs, including General and Engineering Expense, Taxes and Insurance.

Intangible Assets, or, more properly, non-physical assets, include Value of Patent Rights, Going Value, Value of Trade Marks and Goodwill, and constitute the major portion of the total value of an industrial property. The method of determining their value is so dependent upon the exigencies of individual cases that it is useless to attempt to outline a general plan for their determination.

Depreciated or Present Value of the inventoriable portion of the plant. This may be determined along the lines suggested by Mr. Morse. The items Omissions and Contingencies, Purchasing Expense, Tools and Tool Expense During Construction, and all of the Collateral Costs, should be depreciated at the same rate as the inventoriable property, i. e., the present value of the inventoriable property divided by its reproduction cost will give a condition per cent which may be applied to the reproduction cost of the items Omissions and Contingencies, Purchasing Expense, etc., to obtain their respective present values.

It is undoubtedly true that some of the appraisals prepared by the so-called appraisal companies contain needless detail, and, furthermore, that the accuracy of inventory is ofttimes more than offset by erroneous assumptions as to depreciation and by too close adherence to standard unit costs. This raises the point that the problems involved in manufacturing-plant-appraisement work are strictly engineering problems, requiring the experience and judgment of trained engineers.

The short-cut methods prescribed by the author, on the other hand, while admirably adapted for his own purposes, are, it would seem, a little too approximate in their nature to warrant their general adoption for engineering valuations. Is it not true that there is a happy medium between these two plans, and that this medium can be best reached by observing, and to a certain extent copying, the methods adopted in the public-utility appraisement field?

Then again, when preparing a reproduction-cost appraisal, why appraise the inventoriable property with great care and accuracy and then omit entirely elements which are just as inevitably a part of the cost of reproducing a property as the cost of the machinery or tools? It is true that the collateral and intangible elements may not be necessary for some of the uses to which manufacturing appraisements are put, but, on the other hand, they are most essential for the determination of fair value in the event of sale or reorganization of properties.

PRODUCTIVE CAPACITY A MEASURE OF VALUE OF AN INDUSTRIAL PROPERTY, H. L. GANTT

R. S. Hale. Many of the questions about cost and value would become simpler if we would give up the idea that there is any abstract "cost" or "value," and instead should work on the basis that the business of the accountant and engineer is to provide data which will make it easier for the executive to answer certain questions, or rather to enable the executive to take action.

The first of the two theories of costs given by Mr. Gantt, by which all the expenses are included in the cost, gives a figure that helps the executive decide whether he can afford to declare a dividend, but is not of very much use for deciding what the expenses will be next year.

The second theory, by which only the expenses actually needed for the production of an article are charged to its cost, gives a figure which is useful in determining what the expenses may be next year, but is not particularly useful in deciding what profit the concern has made the past year.

There is no such thing as an abstract "cost," or if there is it is of no use to any one. Sometimes we want to know whether we have made or lost money during a given period. In other cases we want to know how much our expenses will be increased if we put some by-product on the market. In that case we want to know *only* the real extra cost of the by-product. In still other cases a factory owner may want to know whether he had better shut down his factory for a period, or run it until the market for the product improves. To answer this question he needs an entirely different set of figures than when he is deciding whether or no to build a new factory.

Mr. Gantt's charts are exceedingly valuable, because they help the executive to decide what he could have done if he had had more material, or if he had had more orders, or had had more help. Likewise they help show what could be done if certain idle machinery were disposed of, etc. The cost figures they show are, however, more than useless in some cases; but the same is true of all cost figures.

Practically every theory of cost or theory of valuation helps to answer some particular question, and it is only a matter of logic to say that we shall continue to have new cost theories and new value theories so long as new questions are coming up to be answered.

The point it is desired to emphasize is that abstract "cost" and abstract "value" are of slight or no importance. What the accountant and engineer should give the executive are the figures that will help solve the *particular* questions that are asked in a particular case, and they should not put these figures in any form that would cause them to be used improperly, nor should they give them any abstract name that

would have the same result of misleading the user of the figures.

A. C. JEWETT. The expense of idle equipment shown by Mr. Gantt's chart must be combated, so far as idleness due to lack of orders is concerned, by an intense study of the sales problem. The engineer must direct the sales policies. He must direct the distribution of the products of industry. The consuming power of mankind is not limited. It is the distributing mechanism that is at fault when machinery in the mills and factories is idle and many people lack sufficient food and clothing. When the problem of the proper distribution of the products of industry is solved there need be no idle labor, the cost of living will not be an acute problem, and there need be no complaint about the length of the working day.

This is not new, but it is new for the engineer to give serious attention to matters such as these as a part of his work of industrial management. The solution of these problems and all that they involve is not an easy task, but it is one that no engineer can afford to neglect and that all ought to study earnestly.

J. B. MILLIKEN.[1] To make our position clear, we define the valuation of industrial property to mean the value at which the physical manufacturing property of a corporation is carried on its books. We mention this because Mr. Gantt's paper evidently contemplates a different definition, viz., one including the efficiency of the plant, which involves the value of the organization operating it, which latter he states "is an integral factor in the valuation of an industrial property." We agree with Mr. Gantt, if by industrial property he means all the values which are represented by the capital stock of a corporation, in which case the value of the management is reflected in the profit and loss account and in the market value of the corporation's shares; but the value of an organization cannot properly be reflected in the physical assets of the corporation as shown by its books.

Our view is that the valuation of land, buildings and equipment should be shown on the books of a corporation at their original cost, less a depreciation for use or obsolescence. As a check on our valuations and on our depreciation ratios, we have appraisals made by professional appraisers at intervals of approximately ten years and compare results carefully with our valuations.

In contrast with the *accounting method,* which should be based on actual cost, we believe that *appraisals* should be made on the basis of present cost to replace, less proper allowance for age or for obsolescence, rather than on the basis of original cost, as the latter may be difficult to determine at the time of the appraisal and in some cases may represent more or less than real value, even at the time of purchase. A careful appraisal may disclose excessive original costs, for example, in which case a question arises as to whether the valuation of a given item should be reduced to agree approximately with the appraisal. Great care should be exercised in comparing appraisal values made on the basis of replacement values to avoid taking advantage of an abnormal present cost, such, for instance, as would occur in the case of appraisals made at the present time, due to the very high prices of practically all materials and labor.

We believe that actual cost, whether higher or lower than normal, should be the basis of all values on a corporation's books. It is conceivable that two factories might be exact duplicates and yet show original cost of construction and equipment widely variant. The proper course in such a case is not for the higher-cost company to reduce its valuation, which was its actual cost, but to justify its cost through its profit-and-loss account by increased earnings, if it can do so, so that a comparison of its ratio of net earnings to capital invested in plant may compare favorably with that of its competitor. This method discloses the facts, both of the actual cost of the property and the actual earnings, whereas reducing the cost on the books by a charge against earnings (in excess of reasonable annual depreciation) distorts the facts as to both earnings and assets.

[1] Treasurer, The Yale & Towne Mfg. Co., Stamford, Conn.

J. H. WILLIAMS.[1] Mr. Gantt recommends the use of "constant" cost rates in cost accounting as a means of increasing efficiency of production. The writer would go further and recommend the use of *standard* as well as "constant" cost rates.

By cost *rates* is meant the *percentage* to be added to direct wage and the hour *rates* for the different machines; by *standard* cost rates, rates representing what the cost *should be* as distinguished from what *it is.* The determining of *standard* cost rates is to the same end as time study and the determining of standard methods and time.

Overhead costs and volume of work which are the only factors affecting cost *rates* as here defined are not subject to the same kind of study as operations, but they are equally susceptible of scientific study.

The use of standard cost rates makes possible a daily comparison of the aggregate of the amount charged on the cost records (at standard rates) with the aggregate of the actual cost. Any difference is shown in dollars and cents in the aggregate instead of in the rate. The occasion of the difference, if any, is ascertainable through subdivision of the actual cost into the items used in determining the standard rates.

Through the use of standard rates we are able, as above explained, to determine our profit or loss due to *volume* daily; and by analysis of actual cost and comparison with standard cost, to determine their source.

On the other hand, through using the same *standard rates* in keeping production-cost records, we are also able to determine our profit or loss due to *efficiency* daily by jobs as they are completed. By comparing the actual with the estimated cost of production we are able to determine the operations in which the profit or loss occurred.

In this wise we have a daily statement not only of profit and loss but also a statement as to the several exact sources of profit and loss, and one wherein the difference between the aggregate daily profits and aggregate daily losses will agree with the increase and decrease in assets and liabilities, as shown in the monthly, quarterly, or yearly closing. In no other way can profits and losses be accurately determined daily, or in such a vast number of items. The timeliness and detail of these statements is of the utmost importance in their effectiveness.

R. B. SHEPARD, JR.[2] I am particularly impressed with the paper by Mr. Gantt and heartily subscribe to his dictum that the productive capacity is a measure of the value of an industrial property. Indeed, I will go even farther and assert that productive capacity, taken in conjunction with the desir-

[1] 772 Park Avenue, New York, N. Y.

[2] Office Engineer, Atlantic Coast Line R. R. Co., Wilmington, N. C.

ability of the product from the consumers' point of view, in other words the *earning capacity*, is *the* measure of value, and the only measure unless natural economic conditions have been artificially disturbed. It is remarkably significant that most of the valuations heretofore made have had as their object not the determination of absolute value, but rather the ascertainment of a limit below which public bodies could not arbitrarily depress value through interference with charges for the commodities produced. Granted the power of the public to regulate charges for service rendered by so-called public utilities, subject only to constitutional restraint against confiscation, the only unassailable position open to public utilities in the protection of their interests seems to be that confiscation results when earnings are so reduced by arbitrary action of regulating agencies that fair returns on the capital employed are denied, and the cost of reproduction seems to afford the readiest measure of the sum of capital, or capital equivalent, engaged in the service; hence the disproportionate importance to which the estimated cost of reproduction seems to have attained in current schemes of valuation. To the owner the cost of reproduction does not signify value but is definitely related to the cost of the output of his plant. For his business to be profitable, it must yield a sum sufficient to meet all costs of operation and leave a balance from which to pay interest on the confined capital and a profit. The value is commensurate with the size of this balance, not with cost, or capital equivalent.

The term "cost of reproduction" should, in the writer's opinion, be interpreted to mean the total investment which would be required to replace the object under consideration, including working capital, development costs, etc., etc.; that is, the absolute sacrifice, expressed in terms of money, which would be required for present production, in its entirety, of the completed and operating utility. This is a somewhat more comprehensive definition than is generally attached to the term, but it is justified by the economic functions of the estimated cost of replacement.

For the ascertainment of absolute value recourse must be had to the balance sheet, the past history and the future prospects of the business. The balance sheet does not disclose the value in stated terms, but it furnishes the data as to results of operation and the present financial condition of the business on which the calculation of value must be founded. The value has no fixed relation to the investment. It is, of course, affected by the judgment used in making the investment, the efficiency of the organization, the confidence of the purchasing public, the general condition of prosperity and enlightenment of the community, etc., but these are matters more for the consideration and activity of the managers than of the appraisers, especially as their practical effects are reflected in the balance sheet and enter, along with all other influential facts, into calculations based on data taken therefrom. No definite conclusion as to value could be drawn from the study of operations for one or two years, but the examinations should extend over at least a decade in order that periods both of depression and of prosperity could influence the findings.

This method of valuation is applicable to those industries only which are more or less free to respond to economic influences. For others, subject to regulation and price fixing by external agencies, purely arbitrary methods must be evolved if the valuations are to enter into the contest or construction of rates of charge. To meet such a situation, the industries must claim the right to profitable operation and contend that profitability ceases when the earnings are not sufficient to pay all costs, including interest at reasonable commercial rates on total capital equivalent and, in addition, yield a profit in proportion to the size of the business handled. This is the rock bottom of permissible depression. The criterion should, in equity, be the relative extent to which the regulated, as compared with unregulated, industries are permitted to participate in the general prosperity and welfare.

F. J. Cole. Mr. Gantt does not state whether the items in his idleness expense chart are a copy from an actual day's run at some mill or typical. It is significant, however, that out of \$1969 total cost of idleness, \$1630, or 83 per cent, is chargeable to lack of material or to poor material.

One of the principal sources of expense in the production of any manufactured article is the loss due to an insufficient supply of material, either in not having it at the machines when needed in sufficient quantities, or it being of improper quality.

Where many kinds of materials are used and their quality is more difficult and complex, more systematic work is required in the purchasing, inspection, tracing and delivery of such materials in order to avoid serious delays.

Proper scheduling of events or processes in the making of manufactured articles is most necessary in order to determine the correct anticipation of dates when things must be *done*. This scheduling includes the dates for ordering and delivering of material, inspection, tracing shipments and manufacturing operations of various parts and processes so that the doing of the necessary events is maintained in their proper sequence.

Using all the machines all the time is most economical, but whether it can be done always depends upon many conditions. A surplus of machines is sometimes required to take care of variations in product, where the character of the work varies considerably with different articles of the same general class which are being manufactured.

A daily statement of the losses in dollars and cents incurred through idle machines, idle processes, caused by the percentage of time they are idle, must be a great object lesson to a management in calling prompt attention to the monetary loss caused by idleness in operating below maximum capacity. The idleness expense chart proposed by the author shows at a glance the loss in values, in percentages of idleness, and their cause.

A GAS PRODUCER FOR BITUMINOUS FUEL. O. C. BERRY

Godfrey M. S. Tait. The methods used by the author for the determination of the tar content are all highly practical as applied to the experimental apparatus used, but would, of course, have to be modified in connection with a test of a plant in regular service.

The author's theory as to the volume of recirculated gas is not original, having been tried with more or less success in Europe, the main difficulty experienced being the power consumed by the blower and the excessive quantity of steam thus introduced—unless some arrangement were provided for connecting the governor on the gas engine to the by-pass blower so as to control same. With low load and the by-pass blower running full capacity, it was possible to lower the temperature of the fuel bed to such a point as to shut down the engine, hence the need of some form of automatic control.

Also the findings, as to clinkers, are apt to be misleading, due to the very small size of the producer in question.

The ideal conditions of draft current in a gas producer consist of a perfectly balanced draft at all loads. Any arrangement to get away from this balanced condition greatly

increases the tendency to clinker in all kinds of fuels, for be it understood that the clinker is first formed by a fissure forming in the fuel bed, and by the concentration of draft through such a channel, with a blowpipe effect that fuses the ash and fuel, and that the only way to prevent clinkers is to so arrange the fuel bed that the tendency to form such fissures or "pipes" is reduced to a minimum. This is best accomplished by using fuel beds of generous dimensions and grates that insure equal distribution of the draft current to all parts of the fuel bed at all loads.

In practice it will be found that the resultant increase in efficiency due to the fixation of the tarry vapors of the gas, rather than to wash them out and waste them, is much less than would be expected. If such figures have been worked out by Mr. Berry, the results would be of interest.

Personally I rather lean to the construction of bituminous producers along the line of simple single-zone up-draft, with attached tar washers, as being more adapted to the hard usage of practice, and have in mind a single 400-hp. up-draft, balanced-draft producer, operating on Illinois slack, costing 85 cents a ton delivered, said coal having 4 per cent sulphur content, 22 per cent ash, and 38 per cent volatile matter (10,300 B.t.u.). This producer was installed without any spare unit to help out, and has operated 24 hours per day since August, 1910, using 1¼ lb. of coal per hp-hour. I mention this plant as a case in point on the clinker question, as this fuel had a bad reputation in that respect (as well as others).

Also as to the reduction of CO_2 to 2CO, my own experience indicates that perfect reduction occurs at 1800 deg. fahr., provided that the draft velocity is sufficiently low to allow the time necessary for the reaction. The faster the flow of draft through the fuel bed, the higher must the temperature be for this reason.

Mr. Berry should continue his investigation under conditions entailing more commercial conditions, variable load, without special attention, and noting the possibility of keeping the gas tar-free during such variations without undue attention and the effect of large grate areas; for example, in producers 10 ft. inside diameter, for all producer builders have had the sad experience of discovering that the design that was most successful at 36 in. diameter was far from such on twice that diameter, etc.

C. M. Garland. The studies recorded in Mr. Berry's paper are very interesting and the methods of investigation, together with the design of the producer, are both novel and ingenious. There are several points brought up in the paper, however, which the writer feels have not been sufficiently described and on which further information would be very desirable.

Regarding the removal of ash and clinker from the producer: from the drawing it would seem that the burner for the recirculating gas takes up a large portion of the grate area. It would also seem that this burner would be in danger of clogging through an accumulation of ash. Regarding the formation of clinker: the combustion of the recirculating gases, while it would undoubtedly destroy the tar, would, however, produce a high temperature in the ash zone which would greatly facilitate the formation of clinker, even with fuels which would not clinker in the ordinary producer. Due to the recirculating of the gases and the high temperature, which are apparently maintained even in the coking chamber of the producer, the clinker formation might begin very high in the producer. In this connection temperatures through the fuel bed and of the gases leaving the producer would be very interesting. The removal of the gases from the side of the producer is another element that would tend to cause the formation of clinker, particularly around the side walls.

Data on the calorific value and the composition of the gas from the producer would also be very desirable. The design would unquestionably eliminate tar and produce a gas of low calorific value. While the gas of low calorific value, in so far as power is concerned, is not objectionable, the power end of gas-producer work today is a comparatively small end of the work and is more than likely to decrease rather than increase.

The ideal to be approached in the elimination of tar is a producer in which the tarry products are converted into fixed hydrocarbon gases which would raise the calorific value of the gas instead of lowering it. The demand today is for a producer gas to replace fuel oil. This gas must have a high calorific value in order that high furnace temperatures may be produced.

MR. BERRY'S CLOSURE

O. C. Berry. Mr. Tait calls attention to the methods used in testing for tar. It is very important to know that the gas leaving this producer is entirely free from tar at all times. The method used in making this test is a very searching one and can be applied continuously and without difficulty in any power plant where either live steam or compressed air is available. It consists in maintaining a vacuum of about 20 in. of water inside of a large glass bottle by means of a steam or an aspirator. The bottle should have a wide mouth closed by a stopper. To this stopper is attached the support for a slip of white cardboard. The gas to be tested for tar is led into the bottle through a glass tube. This tube is drawn down to a small opening at its lower end and bent so as to cause the gas to impinge against the paper at right angles and at a high velocity. The presence of the slightest trace of tar in the gas will cause a brown spot to form on the cardboard immediately. This method is very easy to apply, and has the advantage of being very searching and at the same time very quick to react.

I feel that if Mr. Tait will make a closer study of the European producers he will find that they have not been worked out along the lines here presented, though some of them have been very similar. In some cases I have had a hard time to see for myself why the older producer should fail and my own be worthy of success. There has been a reason in each case, however, even though the search for it has caused some anxiety on my part in the early stages.

The work of O. Boudouard, published in the Comptes Rendus de l'Académie des Sciences in 1899 and 1900, has been widely referred to. It would seem to indicate that a temperature of 1800 deg. fahr. is sufficient to decompose the CO_2. The element of time has been left out in this work, however, as is shown by the later work done by J. K. Clement, L. H. Adams, and C. N. Haskins for the Department of the Interior, U. S. Bureau of Mines, and published in their Bulletin 7. Here it is shown that at a temperature of 1832 deg. fahr. the gas must be in contact with coke for 123.2 sec. in order to decompose 78.4 per cent of the CO_2. This is entirely prohibitive, as Mr. Tait will see.

I am sorry to be unable to present a detailed sketch showing Mr. Garland just how the gas burner avoids clogging up with ash. The removal of the ash and clinker is as easy to accomplish in this plant as it is in the standard anthracite plant, and the burner is so designed as to avoid any possibility of clogging up, and never has to be cleaned.

The burning of the recirculated gas tends to lower rather than raise the temperatures met with in the combustion zone of the producer, and has never been the cause of the formation of clinkers. The formation of clinker in the coking zones of the producer is unthinkable, as the temperatures there are below 1200 deg. fahr., while it is a poor coal having an ash with a fusing temperature as low as 2350 deg. fahr., while good coals will not clinker below 2750 deg. fahr.

The heat value of the gas from this plant seems to vary between 125 and 150 B.t.u. per cu. ft., the same as anthracite gas. The high heat values reported in connection with producer gas from bituminous fuel are due quite largely to the presence of tar vapors in this gas, and would be impossible without these vapors. Such a gas is ideal for some types of furnace work, but cannot be used in an engine.

Mr. Rathbun takes exception to the cleanliness of this gas. He knows that the gas from an anthracite plant is the cleanest gas that can be gotten from any type of gas producer, and is also the easiest to separate from what little dirt it does contain. The gas as it leaves this producer is in a class with anthracite gas. It is not clean enough to use in an engine in the condition in which it leaves the producer, but it is the easiest gas to clean that there is.

Mr. Smith is correct in his statement that it will take considerable fixed carbon in the coal to reduce all of the CO_2 and H_2O formed by the combustion of a large amount of volatile matter. It is probable that not all of these gases are completely burned. The tars can be completely destroyed by passing them through an incandescent zone, and some of them are probably eliminated in this way. As a matter of fact, nearly all of the tests on this producer have been made with Indiana and Illinois coals, having about 8 per cent moisture, 35 per cent volatile matter, 49 per cent fixed carbon, and 8 per cent ash. No trouble was experienced in keeping a sufficient bed of coke with any of these fuels.

Whether Mr. Chapman's objection on the score of a deep fuel bed would hold in the case of a larger plant, is problematical. In the case of the plant here shown it is 4 ft. deep, which is not too deep to poke with ease.

Reliability in a producer of this character cannot be established by a series of laboratory tests. It requires years of use in many power plants. I hope that the future may establish the predictions which the laboratory tests have lead us to make for the future of this type of producer.

THE RATIO OF THE SPECIFIC HEATS AND THE COEFFICIENT OF VISCOSITY OF NATURAL GAS FROM TYPICAL FIELDS, ROBERT F. EARHART

H. B. BERNARD. Due to the many features encountered in piping natural gas, such as condition of pipe, type of joints, bends, temperature changes, etc., it is doubtful whether Professor Earhart's determinations are of any value outside of the laboratory. For practical conditions, the formulæ derived by T. R. Weymouth from numerous observations and published in Vol. 34 of the Transactions of the Society are unquestionably of sufficient accuracy in problems involving the flow of natural gas.

Referring to Table 1, it appears that the coefficients of viscosity are computed from the coefficient of viscosity for air and the relative coefficients of viscosity as determined on the following page. It is unfortunate that the author has neglected to give sufficient data to permit the checking of these values by the formula preceding the table.

In determining the relative densities by an effluxometer, the densities are in the ratio of the squares of the times of efflux. In view of the fact that the coefficients of viscosity are in the ratio of the times of efflux, the densities should be as the squares of the relative coefficients of viscosity. Using the latter values as given in Table 1, the computed densities as compared to those in the tables are as follows:

Computed.......	1.000	0.593	0.533	0.563	0.540	0.563
From Table 1...	1.000	0.682	0.660	0.660	0.690	0.666
Computed.......	0.504	0.578	0.563	0.672	0.689	.....
From Table 1...	0.585	0.755	0.678	0.755	0.770	.....

P. F. WALKER. The author uses in his title the words "ratio of specific heats," and throughout his discussion shows that he is assuming that this ratio and the value of the adiabatic exponent are identities.

The statement is made at the outset that this paper and the experimental work on which it is based constitute an extension of an earlier paper dealing with the question of the variation of natural gas from Boyle's law. In that paper the joint authors indicate a very marked deviation of the gas from the laws of perfect gases. While the numerical values shown in that paper are excessive, being made to appear large because of some unexplained fluctuations at low pressures which other experiments do not corroborate, it is true that the substance differs materially from a perfect gas.

It is not necessary to go through the steps of the mathematical proof of the principle that for a perfect gas the adiabatic exponent is the ratio of specific heats. It has been my observation on several occasions, however, when questions on this matter were up for discussion, that it is necessary to remind engineers of the fact that the statement applies only to perfect gases. It seems to be an ingrained notion in the minds of technical and scientific men that the adiabatic exponent must be the ratio of specific heats. This is far from being the truth, however, when the gas is of such a character that it fails to follow the laws of perfect gas to such an extent that the variation is worthy of notice. The point brought out in the previous paper by the author, and in substance fully attested to by all who took part in the discussion, is that this gas in its behavior does vary materially from the laws of perfect gases, and hence it must follow that the value of the exponent found for an adiabatic cannot be taken as the ratio of specific heats.

This point is of significance, provided the purpose of the investigator is to discover facts with reference to specific heat. We need not enter at this time into a discussion as to which is the important thing to be determined. Every contribution to our knowledge of matters in this connection is valuable, and we should be grateful to Professor Earhart for having brought this interesting and instructive investigation to our attention.

SANFORD A. MOSS. While natural gas may depart considerably from the perfect-gas laws, at high pressure, the departure at pressures close to atmospheric cannot be very serious. Hence the computation of density and of specific-heat ratio from gas analysis will give reasonably accurate results.

I have made such computations for the various samples given by Professor Earhart in his Table 1, using the volumetric analysis there given. I obtained values for the density and specific-heat ratio which differ greatly from experimental values tabulated by Professor Earhart.

The method of computing density or specific gravity of a mixed gas from the volumetric analysis is well known. It consists in multiplying the percentage of each component by

density of said component at standard conditions, and adding the results. A sample computation of density is given in Columns *C* and *D* in Table 2. The values of specific heat at constant pressure and specific heat at constant volume can be found in a similar way, using, however, analysis by weight instead of analysis by volume. The ratio of the specific heats of the mixture as thus computed gives a value which can be used to compute velocity of sound, etc., and which should agree with the experimental values of Professor Earhart's n.

In other words, if we have a gas mixture containing various components whose individual specific heats at constant pressure are c_p', c_p'', etc., and whose specific heats at constant volume are c_v', c_v'', etc., and if the percentages by weight of each of the components are x', x'', etc., then it can be shown that the specific heat ratio for the mixture is

$$n = \frac{x' c_p' + x'' c_p'' + \quad . \quad . \quad .}{x' c_v' + x'' c_v'' + \quad . \quad . \quad .}$$

This formula is almost self-evident. However, I have given a deduction in *Sibley Journal*, May, 1905, page 311. A sample computation of specific-heat ratio by this method is given in Table 2, Columns *E*, *F*, *G*, *H* and *I*.

In making computations I have used the values of c_p and c_v listed in Columns *F* and *H*, Table 2. All of these values are fairly well agreed upon by various authorities except the value for ethane, which I was not able to find. However, it is well known that for a perfect gas the molecular specific heat or product of specific heat and molecular weight m, is given by

$$c_p m = \frac{1.97}{1 - 1/n}$$

I have used the value of n for ethane given on the first page of Professor Earhart's paper, and obtained c_p by this formula. The value is of course in error due to the imperfection of ethane, but the discrepancy cannot be very large.

I have made computations similar to those in Table 2 for each of the gas samples given in Professor Earhart's Table 1. A comparison with the experimental results of Professor Earhart is given in Table 3. As will be seen, there is an appreciable discrepancy. I do not believe this can be explained by the fact that the gases in question do not obey the perfect-gas laws.

MR. EARHART'S CLOSURE

R. F. Earhart. A confusion of terms seems to have arisen involving the flow of gases through a pipe. The resistance offered to the passage of a stream of gas through a pipe is a complex problem and, as Mr. Bernard has pointed out, is influenced by the physical condition of the pipes, the joints and several other factors. The coefficient of viscosity, strictly speaking, is a measure of the internal friction of the gas and is but a single factor in the problem. In many cases, no doubt, it is less important than others; it is, however, a factor peculiar to the gas itself.

It appears that in some cases the viscosity effect (or computations for "viscosity" by engineers) is taken to represent the summation of a considerable number of factors. Some of these have been taken into consideration by Mr. Weymouth in the article to which reference has been made.

The experiments on the coefficient of viscosity were made with the idea of comparing the single factor of internal friction or viscosity for gases obtained from widely different sources under similar conditions of pressure and temperature and in the same apparatus. The values obtained cannot, of course, replace those found serviceable in practice and which include several other factors, even though in a very loose way they go by the same name; nor can they be expected to give satisfactory density values.

The rate of escape of a confined gas through an orifice is a function of the pressure, temperature, density and coefficient of viscosity. In the effluxometer we compare the densities of two gases under similar pressure and temperature conditions by the rate of escape through an orifice which must be an opening in a thin diaphragm. To obtain density comparisons, the diaphragm must be vanishingly thin in comparison with the size of the orifice. This is approximated by making a small hole in a piece of thin foil, usually of platinum. The necessity for making the diaphragm thin is to reduce the effect due to viscosity.

TABLE 2 SAMPLE COMPUTATION OF DENSITY, WEIGHT ANALYSIS AND SPECIFIC HEATS OF A GASEOUS MIXTURE, FROM VOLUMETRIC ANALYSIS

Natural Gas from Vinton County, Ohio, Line 6, Table 1

Density of air, 0.07638 lb./cu. ft. at 14.7 lb. abs. and 60 deg. fahr.
Specific gravity of gas, 0.05174/0.07638 = 0.6775
n or c_p/c_v for mixture, 0.4690/0.3590 = 1.306

TABLE 3 COMPARISON OF VALUES OF SPECIFIC GRAVITY AND SPECIFIC-HEAT RATIO OF NATURAL GAS BY COMPUTATION AND EXPERIMENT

Line in Earhart's Table 1	Specific Gravity (Density, with Air = 1.00)		Specific-Heat Ratio n or c_p/c_v	
	Earhart's Experimental Value	Computed Value	Earhart's Experimental Value	Computed Value
2	0.682	0.6503	1.238	1.285
3	0.660	0.6278	1.214	1.294
4	0.660	0.6370	1.209	1.305
5	0.690	0.6622	1.210	1.290
6	0.666	0.6775	1.259	1.306
7	0.585	0.5795	1.285	1.318
8	0.755	0.7320	1.293	1.259
9	0.678	0.6870	1.220	1.278
10	0.755	0.7521	1.290	1.300
11	0.770	0.7760	1.224	1.297

Thus, by suitably dimensioning the apparatus, the viscosity effect becomes small and is assumed to be negligible. When, however, we make the diaphragm very thick or for convenience cause the gas to escape through a tube whose length is great compared with the diameter of the opening, the rate of escape is determined largely by the viscosity factor. Practically, when the length of the tube is 200 times the diameter, the viscosity term becomes so large in comparison with the density factor that the density factor is neglected. The conditions which prevail in the two cases are so different that the data

obtained under one set of conditions cannot be treated by the formula applying to the other.

A comparison of density determinations made by different effluxometers indicates that those made in the usual way are not accurate; the discrepancies are sometimes several per cent. The writer is therefore brought to the conclusion that the accuracy of this method is greatly overestimated.

The point raised by Professor Walker concerning the application of the law of perfect gases to the theory of velocity determinations is well taken. The degree of accuracy obtained in the experiment will determine whether the correction factor should be applied or omitted. The value of n is obtained by taking the product of three quantities, one of which is the density of the gas. The density of the gas was determined to one part in five hundred in the laboratory. This is a higher degree of accuracy than conditions really warrant, for gas from any field will show variations from day to day of perhaps one per cent. However, it was easy to determine. This, however, places a limit on the accuracy of the result, and it is not desirable to introduce a correction factor of less magnitude in the other quantities.

The experiment by Mr. Wyer and myself showed that the departures from Boyle's Law were appreciable for several atmospheres' change and were large when the pressure variations were thirty or forty atmospheres. However, when sound waves pass through a gas the pressure changes are from one atmosphere to possibly one and one millionth atmospheres. Even for such a pressure change there should strictly be a correction for deviation from Boyles' Law, which is assumed to hold between the limits of pressure employed.

The application of this correction factor is not justified when compared with the density determinations. The correction applicable in such cases is treated in a very able way by Capstick in a paper presented to the Royal Society of London (Phil. Trans. Roy. Soc. of London, 1894, Part I, Page 1.) Dr. Capstick was determining the ratio n for a series of vapors some of which were but slightly removed from saturation. Under such circumstances the deviations from Boyles' Law are considerable. He made a careful study of the case and found a small correction necessary. The natural-gas products, however, are so far removed from this condition that any modification of the value obtained from direct experiment is not justified.

PULVERIZED FUEL FOR LOCOMOTIVES, J. E. MUHLFELD

C. W. Corning.[1] I am familiar with many of the results from the use of pulverized fuel as stated in Mr. Muhlfeld's paper, having for several months had charge of an Atlantic-type locomotive in first-class passenger service, burning this form of fuel.

Of the many things which contribute toward the lightening of the enginemen's cares in the discharge of their duties, probably the two most essential are the properly working of injectors and the free steaming of the engine.

In all of the runs made by the engine mentioned, it never failed to deliver all the steam pressure required (in the language of the fireman, it is "two o'clock" all the time by the steam gage). In the event of the failure of the injectors it is a simple matter to shut off the supply of fuel until such time as the matter can be remedied and the fire relighted.

A very prominent feature of the pulverized-fuel engine is the fact that the draft appliances need not be changed for different grades of fuel, or climatic conditions of the various seasons of the year. The locomotive has been operated in all kinds of weather, in very heavy rain storms, snow storms, extremely hot and dry weather, and when the temperature was several degrees below zero, and there never was any noticeable change in the steaming qualities of the engine.

Last, but not least, of the many good qualities stated in Mr. Muhlfeld's paper is that of the possibility of enlarging exhaust-nozzle openings. The area of the exhaust-nozzle opening on the C. & N. W. engine has been increased about 40 per cent. In summing up, what is nearest the heart of an engineman is a free-working engine, and this is obtained by burning pulverized coal.

[1] Chief Smoke Inspector C. & N. W. R. R., Chicago, Ill.

W. A. Evans. Only two of those discussing the proposition suggested what has always been the one difficulty in obtaining powdered-fuel combustion under boilers, viz., the difficulty of maintaining the brickwork with its necessity of large combustion space for this form of burning. One of the men stated frankly that his company had experimented with powdered coal, and found when forcing the boiler, as is necessary in locomotive practice, that the brickwork was difficult to maintain. It is hoped that Mr. Muhlfeld will give full account of brickwork difficulties and means by which he would overcome them.

To those who have watched powdered-coal development there was much satisfaction in the apparent success of burning it under a Franklin boiler at the American Locomotive Works in Schenectady, N. Y. That installation seemed to indicate the necessity of large combustion space and slow velocity of fuel and air entering the furnace. These demands are quite contrary to the limited possibilities on the illustrations shown in Mr. Muhlfeld's paper on the application to locomotive boilers. After operating for over two years, to the writer's knowledge there is no evidence that results have been so desirable as to have the other boilers in the same plant equipped with the same fuel apparatus, and two years of experience ought to attract more attention than is evidenced by the lack of further development in the stationary line in this time.

There is further cause for caution on the part of those considering the use of powdered coal in the fact that of the many concerns claiming to produce powdered-fuel equipment and soliciting opportunities to undertake the entire installation, none, to the writer's knowledge, will give a definite guarantee of results.

Lawford H. Fry. Mr. Muhlfeld has shown the economy and advantage of applying pulverized fuel to locomotives designed with a grate for burning lump fuel. It would be interesting if he could tell us what further advantages could be obtained if the locomotive were to be designed from the outset without the restrictions imposed by the necessity of a grate. To see what changes would be involved, consider the difference in the two processes of combustion. In firing lump coal, the fuel is introduced intermittently, being thrown on to a bed of incandescent fuel. The volatile matter is distilled off and burnt in the volume of the firebox. The fixed carbon, or at least the greater part of it, remains on the grate. In order to burn this, a strong current of air through the grate is necessary since, owing to the comparatively small surface of the lumps, it is necessary that they be scrubbed vigorously by the air, using an amount in excess of that which combines

with the carbon during combustion. This process of combustion gives two requirements in locomotive design: sufficient volume for the combustion of the volatile matter, and sufficient grate area for the combustion of the fixed carbon. It is well known that the higher the percentage of fixed carbon, the larger must be the grate, hence the large grate areas necessary for anthracite burning locomotives.

With pulverized fuel the conditions are, as Mr. Muhlfeld has pointed out, entirely different. The fuel is introduced continuously as it is burnt, not intermittently. Owing to the very large surface which each particle of fuel has in the pulverized form, the scrubbing action of the air is not required, and complete combustion can be obtained with the theoretically necessary amount of air, provided the fuel floats with the air for a sufficient time at the temperature necessary for combustion. It is obvious that with the pulverized fuel no grate area is necessary, but there must be sufficient firebox volume and a sufficiently long travel for the flame to allow complete combustion to take place before the gases enter the flues and are cooled below the combustion temperature. It would be very interest if Mr. Muhlfeld could give us some information as to the volume and length of firebox required for a given rate of combustion.

Now coming to the effect which this novel process of combustion may have on locomotive design: So far as the lump-fuel locomotive is concerned, Mr. C. D. Young in discussing locomotive proportions before the Master Mechanics' Association last June, pointed out that the basic steps in designing a locomotive are, first to determine the grate area necessary to give power, and then to settle on the depth of throat sheet which will give sufficient firebox volume for efficient combustion. The depth of throat sheet in conjunction with the diameter of the drivers fixes the diameter of the boiler which can be used with a given loading gage. This all means that the design for the whole lump-fuel locomotive is built up around, and is controlled by, the grate area and the depth of firebox.

Now with pulverized fuel it would seem to be possible to eliminate both grate and throat sheet, and to use a boiler of larger diameter and special design which would give even better results than can be obtained by adapting an existing lump-fuel boiler. I have not attempted to work this thought out in its practical details, but it would be interesting if Mr. Muhlfeld could tell us whether he has considered this phase of the question of pulverized fuel. Of course a special design of boiler along the lines indicated presupposes complete conversion of the road using it to pulverized fuel, but no doubt Mr. Muhlfeld has sufficient confidence to look thus far into the future.

E. H. Stroud. The results reported by Mr. Muhlfeld show a great advance upon the practice of burning lump coal upon locomotive grates, hand-fired, and an enormous saving to the railroads in many ways. Still better results can be had, however, and a greater saving of coal and money be made by abandoning the use of stack draft, and making all the air necessary for the most complete combustion possible carry into the firebox all the coal that has to be burned.

The statement has been made that it would be impossible to find space enough that could be spared upon the front end of a tender for such apparatus as would be required to do this. Such apparatus, however, is available from my firm, in size to fit that space, and it can be built to operate, at variable speed, by either steam or electricity. It is the result of 16 years of effort and I know of nothing but our method of operation which has been really successful under boilers of any kind. We tried the stack-draft method and abandoned it years ago for the very faults shown by Mr. Muhlfeld's locomotives. They save 15 per cent of coal. Our plan saves nearly 50 per cent in stationary boiler plants, where the usual losses are not so great as in locomotives. By our method we are able also to give furnace temperatures from 1800 deg. fahr. to 3000 deg. fahr. and over, and such a low temperature has not been achieved before.

It is evident from Mr. Muhlfeld's showing that the use of stack draft renders necessary for the control of the fire of a locomotive a much more complicated mechanism than is needed for firing by the method and device I have mentioned, which latter performs for powdered coal the same service as the device called a carburetor performs for gasoline: namely, it receives the entire quantity of the two fuel elements, coal and air, and mixes them thoroughly together in exactly the right proportions before they enter the combustion chamber.

It makes no material difference, therefore, whether the locomotive is standing or running, or what its speed may be, or whether there be wind or no wind, provided it be fired by such a stoker; whereas, when depending upon stack draft the circumstances mentioned must necessarily exert a considerable influence, and require the use of a constantly varying quantity of exhaust steam at all times to counteract those influences, thus putting a back pressure upon the cylinders and reducing the efficiency of the locomotive proportionately.

I think it is admitted by most railroad men that the use generally made of the exhaust steam to create stack draft reduces the total locomotive efficiency 25 per cent. Such being the case, the use of the apparatus referred to would give the locomotive one-third more power to use, besides effecting a greater saving of coal and water and the simplifying of the control of the firebox results, because the exhaust steam will not be used to create draft.

J. H. Manning.[1] Mr. Muhlfeld's paper accords with our practical experience with engine 1200, having a boiler the principal dimensions of which are as follows:

Diameter, first course..........................86 in.
Firebox, size.......:..........114 in. wide, 126 in. long
Equivalent heating surface.................5004 sq. ft.
326 2-in. tubes
46 superheater units

This boiler supplied steam to 27 x 32-in. cylinders, and developed through a medium of 63-in. wheels, 60,000 lb. tractive power at the drawbar, carrying 205 lb. of steam.

This company, the Delaware and Hudson, is closely connected with a territory that produces about 80,000,000 tons of anthracite per year. It is not hard to understand that a great deal of extremely fine coal and dust accumulates in the process of marketing. This cannot be burnt on the grates, but, if at all, in suspension in a refractory furnace. For this latter purpose we have available in our neighborhood 550,000 tons per month. This latter and the fact that there were located around us a number of industrial plants successfully burning bituminous coal in pulverized form, encouraged us to build an experimental locomotive of the dimensions stated above, producing approximately 2700 cylinder horsepower. To guard against the possibility of failure, the entire firebox, boiler and locomotive was so constructed that the application of the powdered-fuel mechanism could be readily removed and the firebox, etc., arranged for burning fuel on grates.

[1] Superintendent of Motive Power, Delaware and Hudson Company, Watervliet, N. Y.

We soon found out it would be impossible to burn clear anthracite coal in pulverized form. Due to the low volatile, it would promptly snuff out if the engine should happen to slip or worked extremely hard, and firebox temperature would not permit it to again flash. We therefore arranged a program and determined to start with 75 per cent bituminous and decrease until it was found that this objectionable feature was removed. This was continued until a mixture of 60 per cent anthracite and 40 per cent bituminous was obtained. We find this gives splendid results, the engine steams freely with very little smoke and is very nicely controlled by the fireman to the extent of keeping the engine within three pounds of the maximum pressure continuously without popping under the different operations necessarily obtaining in a day's work with an engine of this character, experiencing no firebox trouble whatever.

Such difficulty as we have had with the pulverized-fuel mechanism for the introduction of the fuel into the firebox has been satisfactorily eliminated and the successful burning of pulverized fuel in suspension in locomotive firebox, to my mind, has passed beyond the experimental stage. It is now a question of economy only and this depends upon the source of supply in a great measure.

MR. MUHLFELD'S CLOSURE

J. E. MUHLFELD. With respect to the points that Mr. Robinson brought out, I would say that he has looked at this matter from a strictly practical standpoint, and, in my opinion, the advantages that he names, through ability for the railway to pool the various grades and qualities of coal that they secure from the different mine operations along their line, reduction in fire building, ashpit and other terminal delays, and the elimination of arduous labor on the part of the fireman, are among the most important items with which the railways are contending today. The advantages of pulverized fuel with regard to all of these have already been demonstrated in road and terminal operation.

Mr. Katte took exception to paragraph *a* under the caption Facts and Conclusions. If, as he states, the electric locomotive and the complete electric installation behind it for the movement of heavy traffic over long distances can be maintained and operated cheaper than the equivalent steam unit, then we would like to have some figures to show it. As the steam locomotive carries its own self-contained power plant, its maintenance cannot be compared with an electric locomotive that does not generate its own power. A fair comparison must cover the combined fixed charge, maintenance and operating expense involved for drawbar horse power per hour.

Mr. Katte felt that the electric installations so far made have demonstrated greater reliability under all conditions than steam locomotives. In reply to this it might be interesting to make a comparison of steam-railway steam-locomotive operation for from 25 to 30-mile runs in the Chicago district with steam-railway electric-locomotive operation for similar distances in the New York district as regards schedule time and regularity and continuity of service, summer and winter. With respect to flexibility of service, a steam locomotive can be operated wherever the gage and strength of the track admit it, whereas an electric locomotive is confined to the electrified section that fulfills its electric-current characteristics and contract-line requirements. In the January 8, 1916, issue of the *Railway Review*, I covered this phase of the subject in considerable detail in a paper entitled The Future of the Steam Locomotive, the majority of the data presented having been obtained from about five years of actual experience with steam- and electric-locomotive operation on the Baltimore and Ohio Railroad.

The point that Mr. Fowler makes about more constant firebox temperature with pulverized fuel is certainly correct, as the firedoor is never opened during the time that combustion takes place, and the liability of a cold shaft of air passing through the firebox, as where coal is burned on grates, is entirely eliminated.

Mr. Young refers to work that the Pennsylvania has done and which, from results obtained with a locomotive in a stationary condition, must have been with entirely different means, methods and processes from what we have developed and make use of in both locomotive- and stationary-boiler practice. Their arrangement evidently concentrates or pockets the heat in connection with the refractory material, and too great a velocity pressure of the products of combustion must obtain in the firebox.

Mr. Young also brought out that the Chicago & North-Western locomotive water-rate performance was exceptionally high. He evidently considered this from a cylinder-horsepower, rather than from a drawbar-horsepower-per-hour standpoint.

With respect to his statement that from 40 to 60 per cent of the fuel consumed by steam locomotives, when coal was being burned on grates, takes place when the engine is not working steam: Our data in this regard, obtained from actual road results, are in accord with his figures. Of course, the more congested the operation on a right-of-way, as for example, during the past few months on various steam roads in the Eastern district in the United States, the greater this percentage becomes.

Mr. Randolph brought out the matter of liability of dust explosions. From the fact that about 8,000,000 tons of pulverized coal are now being burned in the United States per annum, it is thought that general practices with respect to the handling, drying, pulverizing, storing and disbursing of the same have been pretty well taken care of, and the general results with the various cement and industrial plants using this kind of fuel indicate this to be the case. Where we have had our designs of fuel-preparing, handling and burning equipment installed, up to the present time no trouble whatsoever has obtained.

Mr. Basford's idea of prolonging the life of existing locomotives by modernizing them through the application of pulverized fuel was well taken, and an enormous amount of work remains to be done along this line which will enable the reclaiming of motive power that in its present condition is ineffective and uneconomical.

Mr. Baker brought out the problem of smoke elimination, particularly in the larger city terminals where numerous switching and transfer locomotives are used.

The control of not only the smoke, but also of sparks, cinders and popping off, as well as the reduction in the exhaust-nozzle noise is entirely possible and practicable with the development that has already been demonstrated through the operation of the Chicago & North-Western pulverized-fuel-burning locomotive in the City of Chicago.

The items that Mr. Corning brought up were those which appealed to the practical railway operating official as well as to the engineer and firemen in charge of the locomotive, and the benefits to be derived from flexibility in the operation of the equipment and the maintenance of economical working steam pressure at all times and under all conditions, and further the increased tractive power by the enlargement of the exhaust-nozzle area are most essential in that regard.

Mr. Evans brought up the difficulty in maintaining brick-

work, with the necessity for large combustion space in the use of powdered fuel in boilers, and requested data on that subject. The answer is: Reduce the velocity pressure of the combustion gases to the minimum; eliminate restricted areas in the brickwork through which these gases must flow; and bring these gases into contact with heat absorbing surfaces as quickly as possible after the combustion process has been completed. We have found that owing to the rapidity of oxidation large combustion space and brick area are not necessarily essential to effective results.

Probably the reason for Mr. Evans not being able to secure a definite guarantee of results from the use of pulverized fuel from the concerns with whom he has had the matter up, is the fact that until recently very little practical knowledge has been available on which to base such assurances, and that essential means, methods and processes were not really developed along practical lines until the application of pulverized fuel to the most unfavorable condition, i. e., the steam-locomotive boiler, was undertaken.

Mr. Fry brought up the question of volume and length of service locomotive firebox necessary for a given rate of combustion. All of our development work has been done with existing standard designs of locomotive fireboxes and boilers ranging from 48 in. wide by 90 in. long, to 114 in. wide by 126 in. long, and in no instance has there been any difficulty experienced with burning the requisite amount of fuel to secure economical boiler horsepower under the most extreme working conditions. This applies to lignite as well as to bituminous coal and to a mixture of 60 per cent of anthracite slush and 40 per cent bituminous screenings.

The point that Mr. Fry brings up relative to being required, when coal is burned on grates, to build up a locomotive design around the grate-area and depth-of-firebox dimensions, is largely correct, and the burning of fuel in suspension will enable the use of special designs of locomotive boilers, for example, for longer flameway and return tubes, which will permit of utilizing a much greater percentage of the fuel value than will ever be found possible by the burning of fuel on grates.

Mr. Stroud points out the feasibility of securing still better results than what have been obtained by abandoning the use of stack draft. The practical work that we have done along this line has, to the present date, not demonstrated this. While stack draft is not needed to secure combustion results, it is required to produce boiler and superheater capacity and effectiveness, which all-important factors Mr. Stroud has apparently overlooked.

Mr. Manning brings up that on his road a mixture of 60 per cent of anthracite and 40 per cent of bituminous is now giving splendid results in locomotive service. I desire to elaborate on this and state that the 60 per cent consists of anthracite slush, or heretofore waste by-product of mining, and that the 40 per cent consists of bituminous unwashed screenings, all of which is mixed and pulverized.

This mixture gives a fuel of about 15 per cent volatile as compared with the heretofore generally recommended practice of not less than 30 per cent volatile. Furthermore, this result has been acquired with the second type of furnace refractory arrangement tried out, and we feel that the next change in the refractory arrangement will result in the utilization of a mixture of at least 80 per cent of anthracite slush and 20 per cent bituminous screenings, for the reason that no difficulty whatever is now experienced in burning the straight anthracite slush in stationary boiler practice and obtaining the requisite boiler capacity and maximum efficiency.

WATER FOR STEAM BOILERS, ITS SIGNIFICANCE AND TREATMENT, ARTHUR C. SCOTT AND J. R. BAILEY

S. B. Applebaum[1] This paper and discussion confine themselves to the old lime-soda system which has been in use about half a century and from which little that is new can be expected. No mention is made of the "Permutit" process which has so rapidly come to front in the last decade in Germany, France and England, and during the last few years in this country. This is an entirely new departure in water softening and it represents the only real progress made in a considerable period.

The essential characteristics of this process are that the water passes through a bed of insoluble exchange alumino-silicates or zeolites at a high rate, and that in the cold a chemical exchange automatically takes place between the water and this material, whereby all the calcium and magnesium are completely removed and replaced by sodium. It is a rapid chemical reaction between the insoluble powerful reagents and the water, which is a very dilute solution of calcium and magnesium salts. The insolubility of these exchange silicates in water is the essence of the process. Because of this property it is possible to remove all of the hardness from water and to obtain this result by automatic filtration. Why is this not possible with the older process? Every chemical reaction to be carried very near to completion needs a driving excess of the reagent. When we add lime and soda ash to water, they dissolve in the water. To remove all of the hardness we would have to add a large excess which would remain in the effluent. Such an excess would be out of the question from the point of view of operating costs, especially today with soda ash at 2½ to 3 cents per pound; and the high causticity in the treated water would make it unfit for boiler-feed use.

The exchange silicates are placed in the steel filter shells in amounts many times in excess of that required by the reaction. But they are insoluble, and as the water flows through the bed of silicates the excess of the latter drives the softening reaction to completion in a few minutes; the effluent comes out of zero hardness and no causticity is present.

The advantages of this process may be summed up as follows:

1 No chemist is needed to analyze the varying compositions of the raw water and proportion the chemicals accordingly. The water passes through the softening material automatically and can never be overtreated.

2 The reaction takes place in a few minutes. With soluble chemicals three to six hours are needed to allow the reactions to take place. Accordingly large settling tanks are needed. These occupy considerable floor space. The Permutit filters for the same service are small and compact.

3 No precipitates are formed and no sludge has to be removed. The liquors from the regeneration are all fluid and run into the sewer.

4 The only cost of operation is that of the salt used for regeneration of the exchange silicates. It is much more economical than the use of soda ash for the removal of permanent hardness.

5 Finally a water free from causticity and having zero hardness is obtained at all times which deposits absolutely no scale.

[The remainder of the discussion on this paper will appear in the March issue of The Journal.]

CORRESPONDENCE

CONTRIBUTIONS to the Correspondence Departments of The Journal by members of The American Society of Mechanical Engineers are solicited by the Publication Committee. Contributions particularly welcomed are suggestions on Society Affairs, discussions of papers published in The Journal, or brief articles of current interest to mechanical engineers.

Strength of Boiler Furnaces

To the Editor:

In the October, 1916, issue of The Journal, I have read with considerable interest an article by Prof. John Airey, the purpose of which apparently was to expose the inadequacy of the flue formulæ, as regards safety, of the A. S. M. E. Boiler Code by comparing the results of these formulæ with some other flue formulæ promulgated by various authorities.

As the writer has had the advantage of figuring allowable pressures on a very large number of flues covering practically all varieties of sizes actually in use, and also knows from close personal touch with accident statistics in this country that flue failures due to structural weakness as known by theoretical determination contribute a microscopically small proportion of the total number of flues collapsed, he is quite certain that Professor Airey's criticism of the A. S. M. E. Boiler Code formulæ is not warranted. In fact, it seems entirely misplaced, since, judging from what still is actual practice in this country as regards allowing pressure on flues, the A. S. M. E. Boiler Code formulæ appear ultraconservative and their prime virtue is that they are consistent with the most up-to-date and thorough research on this phase of mechanics. Professor Airey's reference to *the danger* of the A. S. M. E. Boiler Code formulæ would therefore seem almost humorous, especially when it is considered that flue failures, aside from those cases of flues that come down due to overheating in connection with excessive amounts of oil entering boilers, are very rare.

It would further appear that Professor Airey's observations of the pressures allowed by other authorities are not correct in several instances, tending to reveal a lack of familiarity with the subject.

Taking up Professor Airey's comment on some of the various rules quoted, I would call attention to the fact that Fairbairn's rule is based on experiments with wrought-iron tubes that were lap-riveted and brazed, so that further allowance for the weakening effect due to a riveted joint is obviously not necessary, especially when making comparisons. This rule is, however, inconsistent in that it permits of pressure determination on flues of any length and produces pressures for long flues that are very low and for the shorter flues excessively high.

The fact has been quite definitely established that for lengths of flues over about six times the diameter, any increase in length for a given diameter does not materially decrease the collapsing pressure.

By a series of tests, conducted on a most exhaustive basis, Prof. R. T. Stewart found this formula for some conditions to err as much as 400 per cent. (Trans. Am.Soc.M.E., 1906, Vol. 27).

In the book written by Hutton no mention is made of the fact whether the flues tested, on which he based his formula, were riveted or welded, but judging from their size and the time this took place, it is fairly safe to assume that they were riveted flues, so that the weakening effect of a joint does not have to be separately taken into account, as it certainly never is in practice.

Hutton's formula has the same faulty characteristics as that of Fairbairn, which has led to the use of the length of riveted sections for L in the formula instead of the total length of flues that are made up in sections by means of lap-riveted girth seams. By doing this, an allowable working pressure that seems more reasonable and which sometimes may still be considered safe is obtained on long flues.

Plain furnace flues of the length given in the concrete case submitted by Professor Airey, namely, 94 in., were rarely made in one length, so that a large majority of the flues at present in use have pressures allowed on them as based on this practice of taking the length of sections for L. In some cases the pressure resulting appears unduly high.

This practice of using the length of sections for L is still followed more or less to this day in the manufacture of inferior grades of boilers and other pressure vessels.

Needless to say, the Code formula gives pressure results considerably lower than the values obtained in the manner just mentioned with Hutton's rule.

The German Government rule is not quoted by Professor Airey in its entirety. This rule reads as follows:

$$t = K \times \sqrt{(P \times L \times D)} + 0.1 \text{ cm.}$$

The constant 0.1 is for boilers in river steamers. For boilers in sea vessels this constant is 0.2. The extra thickness resulting from this augmented constant is required to offset the stronger corrosive action in boilers on board sea vessels due to the possibility of salt water entering them. Quite obviously, for the purpose of making a comparison with the requirements of the A. S. M. E. Boiler Code, which is intended for stationary practice, it would appear that 0.1 is the proper constant to use instead of 0.2, as was done by Professor Airey. On the flue mentioned in the concrete example (29 in. diameter, 94 in. long, ½ in. thick), by using the constant 0.1 the pressure becomes 90 lb. against 75 lb. as calculated by Professor Airey.

Lloyd's rule, $P = \dfrac{89{,}600 \times t^2}{L \times D}$, used to be quite generally employed in the United States for riveted flues, but is now more or less in the discard. Wherever it is still prescribed, as, for instance, in the boiler rules of the City of Philadelphia and other rules that were designed to cover the early practice of boiler construction, the length of the lap-riveted sections may be taken for L, which in some cases has led to absurdly high pressure allowances.

In the practice of applying Lloyd's rule it was never customary to make a special allowance for the character of the longitudinal seam, speaking with regard to American practice at least, and this certainly is not done now in localities where this rule is still used.

The U. S. Government rule (Steamboat Inspection Service) is not identical with Lloyd's rule as stated by Professor Airey,

the latter having been abandoned about 10 years ago. The present U. S. Government rule is

$$P = \frac{51.5}{D}\left((18.75 \times T) - (1.03 \times L)\right)$$

This is the same formula as given in the A. S. M. E. Boiler Code for flues of which the length is 120 times the thickness of the plate or less.

According to this formula the pressure on the flue of the concrete example would figure 94 lb. safe working pressure. There is no stipulation in connection with this formula regarding the weakening effect of longitudinal seams, and consequently the pressures on all boilers in steam vessels where this rule happens to be the deciding factor are never determined making such an allowance; and it may be said in this connection that (to quote the Government Rules) such "plain circular riveted flues, furnaces and cone tops" are quite generally lap-riveted.

The fact that the U. S. Government rule allows for L in the formula to be taken the length of lap-riveted sections causes pressures to be used that appear entirely out of proportion in some cases of very long, thin flues.

The British Board of Trade rule is not correctly quoted by Professor Airey. He quotes it as:

$$P = \frac{75{,}000\, t^2}{(L+1)D}$$

The constant in this formula may be taken at 77,000 for steel flues with single-riveted lap seams. This brings the pressure on the flue in the concrete example up to 75 lb.

There is no provision that the length of riveted sections may be taken for L in this formula, but there is a stipulation limiting the pressure on plain flues to $\dfrac{9900 \times t}{D}$ lb.

Since the British Board of Trade allow various constants in their flue formula relative to the type of joint, it is, of course, not necessary for Professor Airey to make further allowances for the weakening effect of a single-riveted lap seam as he did, as this is taken care of by the constant.

Summarizing the results of the various rules taken up here in the light of their practical application as stated, we get:

	Working pressure
Fairbairn Rule	155 lb. per sq. in.
Fairbairn Rule (modified)	125 lb. per sq. in.
Hutton's Rule	120 lb. per sq. in.
German Government Rule	90 lb. per sq. in.
Lloyd's Rule	99 lb. per sq. in.
U. S. Government Rule	94 lb. per sq. in.
Michael Longridge Rule	157 lb. per sq. in.
British Board of Trade Rule	75 lb. per sq. in.
Average	114 lb. per sq. in.
A. S. M. E. Boiler Code Rule	99.7 lb. per sq. in.

Of course, as pointed out in the foregoing, the fact that some of the above-mentioned rules allow the length of lap-riveted sections to be used for L, in the case of flues so constructed, changes the values of pressure as given considerably; if, for instance, the flue of the concrete case under discussion were made in three sections that were joined by single-riveted lap girth seams, we would get allowable working pressures as follows:

	Working pressure
Hutton's Rule	208 lb. per sq. in.
Lloyd's Rule	296 lb. per sq. in.
U. S. Government Rule	209 lb. per sq. in.
Average	238 lb. per sq. in.
A. S. M. E. Boiler Code Rule	99 lb. per sq. in.

It is particularly in this feature of taking for L in the various formulæ the length of riveted sections, that the A. S. M. E. Boiler Code rules are a marked improvement, as this is specifically prohibited for the Code formula. (See interpretation by the Boiler Code Committee in Case No. 22, The Journal, January 1916, Page 44.)

It is extremely doubtful whether in the majority of cases one is justified to consider the reinforcing effect of a single-riveted lap seam connecting the sections of a riveted flue, sufficient to disregard the total length of the flue and simply consider the greatest length as that of one section, the same as is done when the sections of a plain furnace flue are joined by the Adamson-ring construction or similar reinforcement, especially so when such flues built in lap-riveted sections are quite long, say 5 or 6 times the diameter.

A few examples of actual flues may serve to further show the conservative amount of pressure allowed by the A. S. M. E. Boiler Code formula and what it has heretofore been quite generally the practice to allow, by taking for L the length of sections, according to Hutton's, Lloyd's and the U. S. Government rules.

58½ In. Length. 2 Sections. 26 In. Diameter. ⅜-In. Plate

	Working pressure
Hutton's Rule	135 lb. per sq. in.
Lloyd's Rule	198 lb. per sq. in.
U. S. Government Rule	163 lb. per sq. in.
Average	165 lb. per sq. in.
A. S. M. E. Code Rule	103 lb. per sq. in.

88½ In. Length. 3 Sections. 24 In. Diameter. ⅜-In. Plate

	Working pressure
Hutton's Rule	146 lb. per sq. in.
Lloyd's Rule	213 lb. per sq. in.
U. S. Government Rule	176 lb. per sq. in.
Average	178 lb. per sq. in.
A. S. M. E. Code Rule	72 lb. per sq. in.

100½ In. Length. 3 Sections. 24 In. Diameter. ⅜-In. Plate

	Working pressure
Hutton's Rule	137 lb. per sq. in.
Lloyd's Rule	188 lb. per sq. in.
U. S. Government Rule	167 lb. per sq. in.
Average	164 lb. per sq. in.
A. S. M. E. Boiler Code Rule	63 lb. per sq. in.

Friction Screw Presses

To the Editor:

In the July, 1916, issue of The Journal attention is called to an article treating Pressure Developed by Friction Screw Presses, which appeared in one of the trade papers.

While my firm furnished the author at his request some photographs showing the presses it manufactures, I do not

wish the impression to prevail that the theory developed covers our conception of the subject, and that the value of our product be gaged thereby.

Practically every deduction of the author is wrong and the readers of The Journal may be misled by this article.

The formula for the coefficient of efficiency of the screw is unnecessarily complicated and moreover not correct as it assumes that the end-thrust friction acts on a lever r_2 while only $2r_2/3$ should be used.

The formula should have the following form:

$$N = \frac{t_g\ \alpha}{t_g\ (\ \alpha + \varsigma\ ) + \dfrac{2\ Fr_2}{3\ v_1}}$$

α = mean angle of thread.
ς = angle of friction.
F = coefficient of friction.
r_1 = radius of screw.
r_2 = radius of thrust pivot.

The other formulae, such as those of the energy of the flywheel and pressure developed, are also incorrect.

In the example the author accomplished the remarkable feat of calculating the pressure developed by a press by using a formula containing a constant based upon the dimensions and physical properties of the workpiece, and obtains this constant from the dimensions of the press.

Newark, N. J. E. W. Zeh.

Systematic Committee Work in Technical Societies

To the Editor:

The paper submitted by Mr. Hathaway on a Proposed Plan for the Activities of the Machine Shop Practice Sub-Committee of The American Society of Mechanical Engineers[1] contains certain suggestions that have a far wider scope than his title indicates. While, therefore, the discussion below has been brought out by his paper, I would prefer a more representative title, such as Systematic Committee Work in Technical Societies, with Special Reference to Research Work.

Mr. Hathaway says: "The proceedings of such (scientific and technical) societies should provide authoritative and usable data covering the entire range of activities in their respective fields."

Farther on Mr. Hathaway, in elaborating on his idea, says: "A second and even larger undertaking would be the prosecution along predetermined lines of research that would result in definite advancement of the art. At present this is almost entirely left to the enterprise of individuals or companies and there is no coördination of effort."

To a certain extent work of this sort is already being carried on by various societies, including our own. In order to write more by the card I shall confine myself at first to our own work.

We have within our Society:

The Committee on Technical Research. This is the logical agency to which investigation and experimentation for advancing the arts should be entrusted. Special work is naturally carried on by suitable sub-committees created from time to time and existing until their work is completed and gathered into a final report. The main Committee itself should be a permanent or "Standing" one.

We already have a *Research Committee.* As a research committee it is and can be little more than a name. Research and no funds make a poor combination. That is a joke and a rather *poor* joke at that, whether taken in the literal or punning sense. This is no doubt partly because the Committee is not active and does not ask for adequate funds, and it probably does not ask for funds because it is doubtful of those being granted. Inverting the old saw is also a truth: "Ask not and ye shall receive not." It is expecting too much of a Finance Committee to have to provide in its budget, already unable to comply with demands, for funds not asked for. Even so, the Finance Committee does recognize the Reseach Committee's needs by providing the munificent sum of $300.00. (See the report on page 1018 of the December Journal.)

The various *Standards Committees* provide another agency within our Society that does sometimes concern itself with certain phases involving research, but in too haphazard and uncorrelated a manner to secure the best work at the least cost. While standardization is necessarily based more or less on research, research *per se* is not a function of standardization.

Special Committees are occasionally appointed to deal with certain definite subjects, not standards. In much of their work they could be aided by an adequate Research Committee.

A Suggested Plan. We already have a Research Committee. This should be a general supervising committee, not one that actually carries on research. It should originate or pass on projects for research brought to its notice and advise the Council as to the creating of sub-committees, each to deal with one special line only. It would supervise the work of the sub-committees and the expenditure of funds allotted them. It would, on occasion, bring about coöperation with other bodies from other societies, and secure coöperation of the Committees of our own Society, such as certain Standards and other Special Committees. As to funds, these should be allotted as liberally as our budget permits; it is reasonably fair to assume that funds will be furnished for researches that have a special as well as a general interest, without taxing the Society's budget. Care and tact will have to be exercised to guard against the Society's being improperly used and exploited and lending its name to private enterprise.

Precedents. Attention has already been called to the existence of these within our own organization, though limited, fragmentary and without real unity of purpose. The situation is similar in other societies. The British engineers have come nearer to good coöperation research in connection with the work of their Engineering Standards Committee, made up of representatives of the large engineering societies, coöperating with the great engineering firms and with the government.

Probably no one technical society comes nearer to taking care of the problem than the Verein Deutscher Ingenieure, possibly because that society has funds sufficient to enable it to carry on investigation. I can speak with some degree of familiarity of one example that comes within my personal knowledge and of which I was reminded by Mr. Hathaway's reference to Mr. Fred W. Taylor's work reported in his paper On the Art of Cutting Metals. In the early days when Mr. Taylor's high-speed steels, as well as those of Boehler Bros. and the Bismarck Huette, began to attract the attention of the builders and users of machine tools, the Verein recognized their enormous potentialities. A committee was formed, at first under the writer's chairmanship, and a program of experimentation was laid out. Uniform report sheets were dis-

[1] The Journal, December 1916, page 972.

tributed among the largest machine shops about Berlin, and on these was recorded during six months the tool history of all the regular work going through those shops. This enormous mass of data was then classified and digested. (Owing to the writer's being too fully engaged, he relinquished the chairmanship to the very able direction of Mr. Lasche, chief engineer of the Allgemeine Elektrizitäts Gesellschaft.) This gave exceedingly valuable information in connection with the average as well as the highest type of then existing machine tools. The ultimate possibilities of the steels as they were then were determined by a series of tests carried out directly under the writer at the works of the German Niles Tool Works Company, on heavy machine tools specially arranged with a very wide range of speeds, feeds and power. Special steel ingots for turning down were provided and many tons were reduced to chips. With these tools also researches were carried out along lines indicated by the digest of the data gathered in the various shops.

I refer to this somewhat at length to draw attention to the fact that it has been recognized by at least one engineering society that research of this character is quite within its province, that it should be coöperative rather than left to individual effort, that it can be effectively carried on by such coöperation, and that effective aid and coöperation for the general benefit can be secured also from private interests which are quite ready to recognize that though their aid is to some extent altruistic, it is also, as are most truly altruistic efforts, directly beneficial from a personally selfish viewpoint; and that is why such research work, properly undertaken and organized, may count on financial support that need in no way embarrass the Society.

Impact or Shear Tests

To the Editor:

In a letter on Impact or Shear Tests published on page 1001 of the December, 1916, issue of The Journal, Mr. John Younger quotes myself as pointing out, in a paper before the American Society for Testing Materials, that "it was very strange that ingot iron or very-low-carbon steel showed greater energy necessary to shear than did the higher-grade chrome-nickel alloy."

The exact words of my paper on Impact Testing, read before that society, were as follows: "By comparing Tables II and III it will be seen that there is no easily discovered relation between the results of impact tests and those of tension tests. For example, ingot iron with low tensile strength and high ductility gives nearly as good impact results as the chrome-nickel steel of high tensile strength and rather low ductility."

No other comment is needed than a comparison of the above quotation with Mr. Younger's indirect quotation.

Annapolis, Md.

Engineering Societies and Public Affairs

To the Editor:

Mr. W. Herman Greul's communication appearing in the November issue of The Journal has my decided interest. Mr. Greul has apparently entirely missed or, rather, misconstrued my suggestions on "the relation of engineering societies to public affairs." As a matter of fact, Mr. Greul is far more in accord with my position than he seems to realize. Nowhere did I suggest that the engineer or the engineering societies should adopt the "wait-till-they-ask-me" position.

Quite the contrary, it is distinctively the function of the engineering societies to concern themselves with public affairs and I have advocated that, but to restrict that concern to the engineering phase while steering clear of politics.

Possibly the strongest proof of this situation is the A.S.M.E. Boiler Code matter that I also cited in my original communication. The American Society of Mechanical Engineers, in association with other engineering bodies, not only did not wait until it had been approached, but it took the initiative in working up a basic engineering code governing the construction of boilers. The thing that the Society did not do in this connection, and upon which the Society has gone on record as being outside of its province, was the formulating of laws relating to the adoption of the Code by municipalities and legislatures.

Those who are most familiar with the work that the Society did do in the working up of this Code, those who know of the weeks of continuous sessions, frequently lasting late into the night, that the original Committee and its consulting committee held, will be most emphatic in their conviction that the Society did, of its own initiative and from within, undertake most vitally constructive work connected with public affairs.

It is rather difficult to see just how this attitude of the Society can be interpreted as the engineering societies' being "afraid they cannot measure up to the requirements of such a progressive attitude" and "stay on our pedestal where we will not encounter the difficulties of constructive, aggressive work." Surely if ever any constructive work was done by an engineering society, this Boiler Code deserves that name; such constructive work was distinctly and most decidedly constructive engineering, and it would be difficult to see in what way the engineering societies can be of more use to the community than along just such lines; and it is work of this sort which was most distinctly advocated in my article.

Henry Hess.

Philadelphia, Pa.

In the *Journal of The Franklin Institute,* January 1917, is described a machine of high precision for testing the speed and efficiency of shutters in photographic apparatus, developed by the research laboratory of the Ansco Company. In this machine a simple method has been found to overcome the difficulty due to overlapping of the image in the case of shutter exposures of more than 1/50 sec.

In *The Engineer,* December 29, 1916, is presented a brief description of reinforced-concrete floating structures which have been widely employed of late. In the past, similar structures were built but they were not intended to float continuously. The article, among other things, recalls the fact that as early as 1912 a pontoon was built for the Manchester Ship Canal 100 ft. long and 28 ft. wide, to draw about 5 ft. 6 in. of water when fully loaded, and to act as a movable pumping plant which is shifted from place to place as may be desired and which is used for pumping material dredged from the canal on to any low-lying land near the banks which it may have been decided to raise.

SOCIETY AFFAIRS

A Record of the Current Activities of the Society, its Members, Council, Committees, Sections and Student Branches; and an Account of Professional Affairs of Interest to the Membership

The features of the month just closed are the meeting of the Civil Engineers in the Engineering Societies Building, noted elsewhere in this issue, and the President's visit to the Sections.

The former means much to your Secretary for the reason that it was his privilege, fifteen years ago, to receive the gift of $1,500,000 from Mr. Carnegie for the Engineering Societies Building. This was addressed to the four engineering societies and the Engineers Club jointly, and on account of the unwillingness of the Civil Engineers to accept at that time, the whole gift was jeopardized until Mr. Carnegie consented to readdress his gift to the other organizations omitting the Civil Engineers.

The President has undertaken to visit all of the Sections at some time during his administration and by that act develop a national interest and spirit. In addition to his visits made to the Sections this month, reported elsewhere in this issue, he has also addressed a number of other organizations, and the underlying thought in all of these addresses has been to emphasize the service of the individual to society.

Calvin W. Rice, *Secretary.*

Council Notes

The regular meeting date of the Council has been changed to the third Friday of the month, in January falling on the 19th. There were present at this meeting, Ira N. Hollis, President, presiding, C. H. Benjamin, W. B. Jackson, C. T. Plunkett, Charles T. Main, Arthur M. Greene, Jr., R. H. Fernald, John A. Stevens, D. S. Jacobus, Wm. H. Wiley, *Treasurer,* Max Toltz, F. R. Hutton, Calvin W. Rice, *Secretary* and R. M. Dixon, *Chairman Finance Committee.*

L. P. Alford, F. E. Rogers and George B. Brand were appointed a Committee on Award of the Junior Prize for 1917, and W. D. Ennis, D. S. Kimball, and F. R. Hutton were appointed a Committee on Award of Student Prizes for 1917. Particulars of these awards appear elsewhere in this issue.

The Council has approved the setting ahead one day of the Spring Meeting, 1917, to permit of a joint session with the Machine Tool Builders Association. The meeting will be held in Cincinnati, May 21 to 24.

The Boiler Code Committee has been reappointed for 1917. This committee has lost by death H. G. Stott and one member by resignation.

The President announced the following appointments on Standing Committees of the Society:

Finance............W. E. Symons, to serve for 5 years
Meetings..........A. L. DeLeeuw, to serve for 5 years
Publication......George J. Foran, to serve for 5 years
Membership..W. C. Morris, to serve for 4 years, Nicholas S. Hill, to serve for 4 years
Library............A. M. Hunt, to serve for 4 years
House..............H. O. Pond, to serve for 5 years
Research........Albert Kingsbury, to serve for 5 years
Public Relations....................To be appointed
Constitution and By-Laws....Ira H. Woolson, to serve for 4 years, Jesse M. Smith, to serve for 5 years
Standardization......Henry Hess, to serve for 5 years

I. E. Moultrop has been appointed on the Board of Trustees of United Engineering Society, to fill the vacancy in the Society's representation on the Board caused by the death of Mr. Stott.

A special committee consisting of J. W. Lieb, F. R. Hutton and D. S. Jacobus was appointed to prepare resolutions in token of appreciation of the signal contribution to the society's work rendered by Mr. Stott in his service as an officer of the Society, as a member of professional committees, and as the Society's representative in many undertakings.

Special resolutions were recorded thanking the Engineering Foundation, and in turn the Founder Societies, for the assistance which has been given to the National Research Council in its work. These resolutions follow:

Whereas The Engineering Foundation, administered by the American Society of Civil Engineers, the American Institute of Mining Engineers, The American Society of Mechanical Engineeers and the American Institute of Electrical Engineers, out of public spirit and with a desire to increase the intimacy of the relations between the research workers and the engineers of the United States, has generously put its whole resources, its office facilities and the services of its Executive Secretary at the disposal of the National Research Council in order to assist the federation and coördination of governmental, educational, industrial and other agencies of research, and

Whereas the assistance of The Engineering Foundation thus tendered has been gratefully accepted; now, therefore, be it

Resolved, That the thanks of the National Research Council for this assistance be hereby expressed to The Engineering Foundation and through it to the United Engineering Society and to the American Society of Civil Engineers, the American Institute of Mining Engineers, The American Society of Mechanical Engineeers and the American Institute of Electrical Engineers, and it is further

Resolved, That the National Research Council reciprocates and hereby expresses the desire for closer relations between the research workers of the United States and the members of the engineering profession constituting the national engineering bodies, and it is further

Resolved, That the Secretary of the National Research Council be instructed to transmit a copy of these resolutions to The Engineering Foundation, to the United Engineering Society and to the governing bodies of the national engineering societies above mentioned.

Attest Cary T. Hutchinson, *Secretary.*

W. B. Jackson, member of the Council and past-president of Board of Directors of the Western Society of Engineers, presented the request of that society that the Council appoint two representatives on the Washington Award administered by the society to be annually presented to an engineer whose work in some special instance, or whose services in general have been noteworthy for their merit in promoting the public good. The President has been requested to nominate two such representatives.

Calvin W. Rice, *Secretary.*

CIVIL ENGINEERS MEET IN ENGINEERING SOCIETIES BUILDING

THE Sixty-Fourth Annual Meeting of the American Society of Civil Engineers, now a Founder Society, was, by invitation of the United Engineering Society, held in the Engineering Societies Building. Plans of the addition to the building to house the Civil Engineers and a model showing how the building will look when completed were available at the meeting for inspection. The meeting was held on January 17 and 18.

In calling the meeting to order, President Clemens Herschel introduced Mr. Charles F. Rand, President of the United Engineering Society, who "welcomed the Civil Engineers to their own home." Mr. Rand said:

"As one who has looked forward very earnestly to this day and who has made a modest effort in favor of the new arrangements, it is a peculiar satisfaction to be the representative of the Trustees of the United Engineering Society and to welcome you on the occasion of your first meeting in this building in which you now own a quarter interest.

"As this is your annual meeting, I cannot take your time for extended remarks, yet it seems proper that I should call attention to a few facts respecting the United Engineering Society with which you are now identified.

"The U.E.S. exists for the purpose of holding the legal title to certain of the property of the Societies of Civil, Mining, Mechanical and Electrical Engineers, and to act for them in certain matters. The value of its property, including real estate, the Library and the Reserve and Endowment Funds exceeds two million dollars, all free and clear.

"The total membership of the four Founder Societies is 29,000 and the membership of associate societies is 23,000, making a grand total of 52,000 engineers who now have headquarters in this building.

"As is well known the U.E.S. stands not over but under the Founder Societies. It is organized to perform for the Founder Societies certain specific acts which are governed by contracts. There is no merger of societies, each retains its individuality. The U.E.S. enables the Founder Societies to coöperate conveniently.

"The Engineering Foundation is a fund of $200,000 belonging to the U.E.S., established for engineering research with a gift from Ambrose Swasey; this fund it is hoped will soon be increased many times.

"The great Library now includes that of the Civil Engineers and contains approximately 75,000 bound volumes and 50,000 unbound volumes. It is believed to be the largest engineering collection in the world. Plans have been made for the development of the Library which contemplate the expenditure of $50,000 annually. At present the societies can only afford to spend $20,000 per year. The Library has an endowment of $100,000. This we hope may soon amount to one million dollars, as the Library needs the income from that sum.

"The United Engineering Society has been established thirteen years. It was originally developed through the efforts of the Societies of Mining, Mechanical and Electrical Engineers. To this organization the American Society of Civil Engineers has joined its strength and prestige and takes a leading part.

"Your new home is being rapidly prepared for you and will be ready during the current year. The six months of intimate association and cordial coöperation we have already had with the officers of your society indicates that a move has been taken of great value and importance to engineers.

"Gentlemen, welcome to your own home."

The professional program of the meeting was devoted to the presentation of the annual reports and the reports from several special committees and the election of officers for the ensuing year. The new officers are: George H. Pegram, president; Alfred Craven, George W. Kittredge, Palmer C. Ricketts and George S. Webster, vice-presidents; George W. Tillson, treasurer, and Charles Warren Hunt, secretary.

Among the reports was that of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and other Public Utilities. This report is the result of five years' work on the part of a committee of nine, who have held forty-eight joint meetings, many of them consisting of three sessions, and who have carried on a voluminous correspondence, aggregating thirteen substantial volumes. This report is of particular interest to our own membership, coming out, as it does, so soon after our own discussion at the Annual Meeting of this important subject. Those of our members who are particularly interested will find this report very helpful in clarifying this subject.

The entertainment part of the program included an inspection of the new Broadway subway in New York City, a visit to Hell Gate Bridge, and an excursion on the East and Hudson Rivers.

THE PRESS ON THE ANNUAL MEETING

THE Annual Meeting of the Society and the papers and discussions were reported by the daily as well as the technical press, some editions assigning prominent positions and considerable space. We believe that the increased attention given by the press reflects in a direct way the increasing importance of the engineer in the affairs of the State, economic as well as industrial. As to the general result of the Annual Meeting, *The Iron Trade Review* says, "In attendance, enthusiasm and general merit of the papers, the meeting surpassed those of past years," with which we are sure our members will be in entire agreement from their personal experience, for this was without doubt the most successful meeting we ever held. In saying this, we must not overlook, however, that there are several factors which contributed to this result, one of which undoubtedly is that to a certain extent these are abnormal times. The European war has acted as a stimulant on our thoughts and energies, we are living in a time of intensified activity, expectant of the future and alert as to what it may bring us. Apart from preparedness campaigns, the reflex action of the war on our national life has been the cause of many economic and industrial developments, some of them taxing the ingenuity of the engineer to his uttermost capacity.

The Chattanooga *News* in its report of the meeting says, "Many people maintain that a great moral and spiritual revolution is now in progress which will change all the thoughts and actions of the world." Although this statement may be somewhat too sweeping, yet it contains some truth. Our outlook and our thoughts are undoubtedly undergoing a change, though we may not even know in what direction, but we are

in a very receptive state of mind at present, which engineers should hail as a splendid opportunity for the initiation and execution of improvements tending to our national advancement; and we believe engineers can be relied upon to do their share in this direction.

In their reports of the meeting, a number of journals and newspapers laid stress on the fact that the field of activity of the engineer is constantly broadening and that he is increasing his influence in all directions. If this means that wherever the engineer steps in, the work will be done more scientifically and more systematically than has been the custom, then this extension of his activity must certainly be welcomed as conducive to the good of the Nation as a whole and should be encouraged in every respect. We believe that the engineering profession will not commit itself light-heartedly to additional responsibilities, but, having accepted them, will not be found wanting. Our Society has always fostered that sense of responsibility in its members which is essential to success. These points are well summarized in *The Iron Trade Review,* which says in this connection; "That the engineer's influence is bound to extend far beyond the conventional limits of the profession was emphasized in the sessions of the 37th Annual Meeting of the Am.Soc.M.E. Scientific management, industrial valuation, safety regulations for cranes and boilers—all subjects outside the old recognized limits of mechanical engineering, claimed most of the attention of the 1500 members and guests of the Society in attendance. The feeling that the engineering profession must take up a large proportion of the burden of national affairs was expressed by several different speakers and the evidence that engineers are eager to assume this added responsibility was furnished by the unusual interest displayed in the subjects of general application." We believe that this accurately expresses the consensus of opinion of the meeting.

Not only is the activity of the engineer extending in all directions, but also the range of subjects before the Society shows a broadening out and extension into the multitudinous ramifications of subjects hitherto somewhat foreign to the engineer. The press took general note of this, *The Iron Age* saying in this connection: "The efficiency of the manager, more about the human factor in industries, the need of a means of collating machine-shop information for the common good, and the undeveloped but necessary place of the mechanical engineer in industrial preparedness were conspicuous topics in the discussions." Thus the engineer not only does things but he endeavors to go to the bottom and find out how to do them best, which in a broader sense means that he is more and more departing from the individualistic standpoint and is learning to view things more from a sociological or national standpoint, even though he would seemingly depart from his customary field of action. "The surprising thing," says the Chattanooga *News,* "was the emphasis placed in many of the papers upon the moral and social aspect." This is a frank recognition of the fact that in the mind of the engineer the financial aspect is giving place to more altruistic ideals. This displacement of finance from supremacy, it will be remembered, was very tersely expressed by Mr. Gantt in his paper when he substituted the "ability to do things" for the "ability to buy things," making the financier give place to the engineer.

With regards to comments on papers before the meeting, the address of Dr. D. S. Jacobus, our retiring president, on Education in Engineering, was very generally quoted and commented on, the recommendations in it receiving unqualified endorsement.

Professor Cathcart's paper on the Development of our Fleet and Naval Stations attracted wide attention. This paper was very prominently announced by such captions as "More Naval Bases Urged," "Charleston Recommended as a Naval Base," "Naval Stations are Inadequate," "Speakers Deplore Lack of Adequate U. S. Naval Stations," "Woeful Unpreparedness on U. S. Coast Depicted," "U. S. Navy far below par in Stations and Destroyers," "South's Lack of Stations is Discussed," "Lack of Bases puts Navy in Peril," "Cathcart's Warning sent to Congressmen;" one of the papers pointing out that it was the best paper produced on the subject in recent years and would certainly receive the attention of the Government. Professor Cathcart's paper is published in this issue of The Journal.

Extensive quotations also appeared from the other papers; there was not a single paper which did not arouse interest in some quarters, though it is also fair to say that some of the papers have not received so far the attention which they merit and it is to be hoped that in due course the technical press will also do justice to these.

PRESIDENT HOLLIS SPEAKS AT CLEVELAND

On January 2, Dr. Ira N. Hollis, President of the Am.Soc.M.E., addressed the Cleveland Chamber of Commerce on the subject of Efficiency and Democracy, in which he advocated, instead of military conscription so prominent before the public in connection with preparedness, a conscription of the whole youthful population to form an army "enlisted against nature." Such an army would, for instance, supply the labor for building the Lincoln Highway across the continent, etc., and there are a thousand other great utilities it might carry out. Dr. Hollis said in part:

EFFICIENCY AND DEMOCRACY

I can hardly claim to bring you a message from New England, as I come from the same side of the Alleghenies as you. My earliest association were with the soldiers of the Civil War and the memories of that time would lead me naturally to avoid war, yet, it is difficult to talk on any subject in America today without some mention of the greatest event in history, made doubly horrible by science and modern invention. We and the whole world are involved and we cannot escape from its consequences.

The great question before the world today is the relation of government to the individual and the attitude of the individual towards his own government. Many of us believe that the whole future of democracy is at stake and that unless democracy can develop as high a national efficiency as autocracy, it is doomed. That is fundamentally the question before the United States today.

What is efficiency? It has expanded as it has become more important in the past few years, and is now applied to nations as a whole. When we take the Century Dictionary definition, namely, "a quality or power of producing desired or intended effects," it is applicable to nations as well as individuals. Another definition is "the state of being able or competent, the state of possessing or having acquired knowledge or skill in any act or profession." In the technical sense the word has a mathematical significance: it is the ratio of useful work to the total energy expended in producing it. This is perhaps the best definition, for it calls attention to the essential of efficiency, the saving of waste in energy and materials. When one stops to investigate our criminal waste of food, our lavish expenditure of time and money on useless things, and our failure to fit transportation into

the distribution of the commonest necessities for great cities, one would almost condemn us as the most inefficient nation on earth.

A few years ago Mr. Frederick W. Taylor undertook investigations to determine with accuracy the best system for workmen as well as for tools. The results ultimately grew into "scientific management," so called by Louis Brandeis, in order to direct the mind effectually to the essentials of the method: viz., getting the maximum return in manufacture for a given expenditure of time, money and effort, by the scientific planning and allotment of tasks to every tool and employee. Under Mr. Taylor's development of the subject we have always the idea of the manufactured product, but the term is capable of a much larger application in relation to communities or nations as a whole. The true meaning of efficiency, in a larger sense, is the regulation of one's life so that society shall receive the maximum return in service and in happiness.

The application of the word efficiency to our government is better brought out in connection with the real meaning of the term democracy. Abraham Lincoln defined it for all time in the words "government of the people, by the people, and for the people." It makes no difference what the head of the State may be called, so long as his definition holds. Presidents and kings alike, are equally powerful, or equally powerless, when the rules are made by the people themselves. After all, there are only two forms of government, one by the few, aristocracy, and the other by the many, democracy.

In discussing the comparative merits of the two governments democracy, as illustrated by the United States, and aristocracy, as illustrated by Germany, Americans are not always judicial. They are either unduly confident or over-sceptical as to the future of our form of government.

Is it true that efficiency is best developed under democracy and that in the long run a nation is stronger against war with the individual initiative there taught than it could be under an autocracy? Any American would naturally say yes, in the belief that men do better what they consent and wish to do, than when they act under compulsion. But we should be utterly mistaken if we judged the German nation by that measure. In contrasting Germany with the United States we have been too quick to take it for granted that German citizens were acting under the compulsion of a military caste. If so, they have been able to hide the evidence of compulsion, because they have freely consented to conscription during the vast military organization under which their people have been prepared for war, and under which their advance in a material way has been beyond the power of the imagination.

Our own country was a very interesting example of the two types of government during the early years of the Civil War. The Southern Confederacy was practically an aristocracy, with a slaveholding class who took all the offices, and a great population of whites and slaves accustomed to guidance by a governing class. At the outset of the Civil War they were more efficient than the North. It took the North a long time to organize, and it was not until after Vicksburg and Gettysburg that the Southern cause began to wane. The Northern armies had gradually been worn down into effectiveness and the administration had gone into the West, the most flagrantly democratic part of the country, for its commanding officers. This experience in our long war seems to justify the claim that democracy is strongest in the long run. I am a profound believer in democracy as Lincoln defined it. If stripped of certain ugly excrescences, it is the hope of man.

The Declaration of Independence states that all men are created equal, and that they are endowed by their Creator with certain inalienable rights; that among these are life, liberty, and the pursuit of happiness. We have by constant dwelling on the word "equality" twisted it out of the meaning that our forefathers intended to give it. As a matter of fact, the Declaration of Independence was the statement of a noble reaction against bondage in a feudal system, and it expresses fundamentally that men should be equal as to opportunity. It could never determine the equality of men as to physical and mental endowments. They are distinctly not equal and never have been, and no fiat can ever make them so. Nature has taken care of that. In our democracy, we should dwell on the equality of opportunity to serve.

On the court house in Worcester is this sentence, "Obedience to Law is Liberty." That obedience to law is a necessary element of true liberty has been the doctrine of philosophers since the dawn of recorded history. We cannot deny it and we know that our country's liberty is less for every violation or disregard of law.

The finest definition of a man's place in our democracy is found in the statement that here he will be permitted to develop himself to his maximum possibility in the service of mankind. Observe the word "permitted" to develop one's self. It signifies that the individual must learn how to use this permission before it becomes really of value to him

How far must the efficiency of the individual give way to the collective efficiency of a large number of individuals, or of the state? An engineer will understand the force of this question, because he is in the habit of effecting compromises in the selection of machinery for manufacturing or power purposes. In steamships, for instance, it is a well-known principle that a screw propeller generates its highest efficiency at a comparatively low speed of rotation, while a steam turbine is quite the opposite in reaching its higher efficiency at a very high rate of speed. When they are coupled together for propulsion, both must surrender something in order that their combined effort may produce the maximum result.

In the same way, every individual of every community should consider his conduct and his work as affecting all others with whom he is associated, and all others who live under the same flag. If his efficiency in business becomes so distorted that it interferes with the rights and the happiness of others, it must be curbed and checked so that the maximum of service and happiness will be found for all.

The chief danger to any democracy grows out of a false standard. We know in our hearts that the ideals of this country are clean and sound, and yet we stimulate enterprise and initiative by an appeal to the most selfish side of human nature. The patent laws, the entry of public land, and the rights to property, all good within limits, have produced most of the litigation because they are based on selfishness; and the worst of it is that few can see any other practicable or possible method of holding society together. It is a false standard and there is something better in our love of fair play, our charity to our neighbors, our passion to pay and our desire to serve. If we can only let them sway us in relation to our own government as in private life, the republic will be safe for all time and democracy will win the earth.

We have a very curious and striking illustration of liberty and efficiency in the acts of the trade unions. In the name of liberty they claim the right to organize against capital and then in the name of efficiency of organization, they demand the most slavish obedience from their members. There is no liberty in a trades union. Capital is not free from a similar failure to consider the true good of the state or community. The virtual control of property in the United States is in the hands of comparatively few men who have until lately paid no attention to public interests. There is little to choose between capital and labor in their indifference to the efficiency of the state and to the combined effectiveness of all. Between the two of them the public has small consideration, except to pay.

Has any healthy and mentally sound individual a place in any community to which he renders no service or where he makes no contribution to the welfare of the state? This sounds like harsh puritanism, and yet it is not when you stop to think about it. There is in machinery a quality known as hunting. It is found in the steam engine when the governor has a high initial resistance. If the speed increases and the governor does not act, the engine will run away until the governor does act; then it will act too much and carry the engine to the other extreme. This bad quality may be improved, but hunting is always present even in the turbines that supply your power and light. The engine is all the time hunting the average normal speed without ever finding it. In many respects humanity is like that, always striving and never attaining.

If I accomplish nothing else than to call your attention to an essay by William James, on the Moral Equivalent of War, I shall be satisfied with my visit to Cleveland. He has given us one of the noblest conceptions of man's future, and best of all the way out of blood and crime. In the first paragraph of his essay he says: "The military feelings are too deeply grounded to abdicate their place among our ideals until better substitutes are offered than the glory and shame that come to nations as well as to individuals from the ups and downs of politics and the vicissitudes of trade. There is something highly paradoxical in the modern man's relation to war. Ask all our millions, north and south, whether they would vote now (were such a thing possible) to have our war for the Union expunged from history, and the record

of a peaceful transition to the present time substituted for that of its marches and battles, and probably hardly a handful of eccentrics would say yes. Those ancestors, those efforts, those memories and legends, are the most ideal part of what we now own together, a sacred spiritual possession worth more than all the blood poured out. Yet ask those same people whether they would be willing in cold blood to start another civil war now to gain another similar possession, and not one man or woman would vote for the proposition."

What relation has this to the state of mind of the American people? We have had no end of discussion about national defense, the Army and Navy, and universal military service. War is clearly in the air and any one of several questions might bring it like a thunder clap. Not one man or woman would vote for it, but we are in the hands of fate. Will it be possible for any nation to remain neutral in the next war, or in this, if it lasts out another summer? I am a believer in thorough preparedness immediately, and yet I am persuaded that we have taken the public mind away from what should be the great ideal of our republic by emphasizing the word "military" at the expense of the word "service." It is service in every direction that is needed, and no young man can discharge his obligation to the state by a few months in camp. The whole matter hinges on a state of mind. Of course military training may form part of any collective training for the service of the country, but it is not the chief one.

Perhaps the settled idea of all this writing is found in the last sentence of the following paragraph: "The martial type of character can be bred without war. Strenuous honor and disinterestedness abound elsewhere. Priests and medical men are in a fashion educated to it, and we should all feel some degree of it imperative if we were conscious of our work as an obligatory service to the state." After all, it is Service that Mr. James is putting forward as the only antidote to decadence.

How can efficiency be promoted in a democracy? We must again keep in our minds the fact that there are two efficiencies: one, the efficiency of the individual; the other, the efficiency of the collective mass. Our efficiency as a whole will maintain the republic, but the efficiency of the individual acting alone will create such division as to destroy it. That of the individual is soundly promoted by complete freedom of speech, complete freedom of choice as to a career, and by a preservation of the ideals of service as distinguished from sense enjoyment. We have the first two of these eminently developed in the United States, but the last has been clouded over. We have leaned too much on literature and art as representing the higher things, in comparison with the utilities of life. As a matter of fact, neither one of them is worthy of consideration if carried to a debauch, and there is something far higher and more ennobling than either. We do not fix our high moral purpose by reading some beautiful piece of literature or looking at some great picture or by making a lot of money on some invention, but we get it by the experience of life, if that experience takes the proper perspective. It is Christ's conception of life and service that will give us efficiency as individuals in dealing with others. We are too easily misled by college professors into the belief that critical study forms the broadening and enlarging developer of man's soul and mind. Colleges have been comparatively inefficient in turning the mind towards that kind of universal service that will create in this country a united nation. The popular idea that colleges are failures in respect to public service is exaggerated, and yet one cannot but feel that they have achieved far less than might have been hoped from their claims of breadth and education.

As to the efficiency of the collective mass, my belief is that Professor James has suggested the best solution possible in the words: "If now there were, instead of military conscription, a conscription of the whole youthful population to form for a certain number of years a part of the army enlisted against nature, injustice would tend to be evened out and numerous other goods to the commonwealth would follow." It is not necessary here to suggest the elements of the warfare against nature; one of them, however, comes readily to mind. Suppose, instead of an appropriation of millions by the government of the United States and by the states to build the great Lincoln Highway across the continent, that the work on this highway were a free gift of our young men, under universal service, we should then have an enduring monument to love of country and an ennobling incentive to the right kind of patriotism. That great artery of commerce and recreation would hold memories of splendid achievement for generations to come and it would always bind the states far better than interstate laws.

The Lincoln Highway is only one of many things that can be offered by the youth of the country. There might be a Washington Highway from Maine to Texas passing through the mountains of Kentucky and Tennessee. The mind can suggest a thousand other great utilities. It has been claimed that service under the flag in Germany and France has served to educate the people. That is a pure preparation for war which has been going on during the past fifty years as the means of educating the masses. I do not believe for one instant that it offers half the stimulus that constructive service in peace would bring to our youth. All the discipline of the army can be found in the working party with the pick and shovel taking the place of the rifle.

The Army never will be in a satisfactory condition until we get rid of the dual control involved in the state-militia idea and substitute for it a citizen soldiery with only a nucleus of men permanently under arms. This involves of course the Swiss system or the Australian system of universal training, beginning in the public school and continuing for 10 or 15 years.

The appropriations are only stop gaps, however, and we must provide a lasting remedy for the loose, flabby ideas of service held by too many voters. Our main task is only begun, that of arousing a national spirit by every means in our power. Industrial preparedness is only a small part of it. Coöperation in everything is demanded, in education, in religion, in the industries and in citizenship, for the purpose of fusing this conglomerate population into a united, efficient and peaceful nation, capable of serving and advancing civilization. Let us do our share.

Junior and Student Prizes

The attention of Junior Members of the Am.Soc.M.E. and of members of its Student Branches is called to the prizes offered each year by the Society for the best paper by a Junior Member and for the two best papers by enrolled members of Student Branches. The former of these prizes is a cash prize of fifty dollars and engraved certificate, and the latter are cash prizes of twenty-five dollars each and engraved certificate.

The rules covering the award of these prizes are given in the Year Book of the Society, the 1917 Edition of which is about to be issued. The last date for submitting papers for consideration by the Committee on Awards this year is June 30, 1917.

Those who intend to participate in this competition should make their plans now so that their papers will be ready in ample time. They should select a subject of practical value and treat it in a simple, correct, clear and forcible manner. A subject might well be a description of a new mechanical invention or piece of engineering apparatus; an account of some original work in the laboratory, shop or classroom; a description of a new and novel piece of mechanical construction; a description of a novel modification to an existing plant; an explanation of plans or methods of proposed engineering work; a summary of present practice in a given mechanical field, or an argument for or against a particular mechanical apparatus, process, construction, etc.

The Secretary will be glad to furnish any information or to give any suggestions to those intending to compete for either of these prizes.

Correction

Mr. R. J. S. Pigott reports that the statement on page 1009 of the December issue that his "later work included the preliminary design and layout of the extension to the Seventy-Fourth Street Station" is incorrect. His work included not only the layout but also the actual construction and testing of this extension.

CANDIDATES FOR MEMBERSHIP

TO BE VOTED ON AFTER MARCH 10, 1917

THE American Society of Mechanical Engineers is an organization for mutual service of over 7700 engineers and associates cooperating with engineers. The membership of the Society comprises Honorary Members, Members, Associates, Associate Members and Juniors, all elected by ballot of the Council. Application for membership is made on a regular form furnished by the Secretary which provides for a statement of the standing and professional experience of the applicant and requires references from voting members personally acquainted with the applicant. The requirements for admission to the various grades will be furnished upon request.

Below is the list of candidates who have filed applications for membership since the date of the last issue of The Journal. These are classified according to the grades for which their ages qualify them, and not with regard to professional qualifications, i.e., the ages of those under the first heading place them under either Member, Associate or Associate-Member, those in the next class under Associate-Member or Junior, and those in the third class under Junior grade only. Applications for change of grading are also posted.

The Membership Committee, and in turn the Council, urge the members to scrutinize this list with care and advise the Secretary promptly of any objections to the candidates posted. All correspondence in this regard is strictly confidential. Unless objection is made to any of the candidates by March 10, 1917, and providing satisfactory replies have been received from the required number of references, they will be balloted upon by the Council. Those elected will be notified about April 15, 1917.

NEW APPLICATIONS

FOR CONSIDERATION AS MEMBER, ASSOCIATE OR ASSOCIATE-MEMBER

Arizona

LANDRY, CALISTE F. A., Mechanical Engineer, Power Plant, Inspiration Cons. Copper Co., Globe

California

BANE, THURMAN H., 1st Lieutenant of Cavalry, U. S. Army, Aviation School, San Diego

Connecticut

EALES, WILLIAM P., Asst. Supt., Engineering and Inspection Div., Travelers Insurance Co., Hartford

District of Columbia

BROOKE, LLOYD A., Designing Draftsman, Ordnance Dpartment, U. S. Naval Gun Factory, Washington

Illinois

CARLSON, ADOLPH G., Chief Engineer, Universal Portland Cement Co., Chicago

HOWIND, H. ERNST, Checker, Mechanical Engineering Office, Illinois Central R. R. Co., Chicago

LINK, MAXIMILIAN W., Assistant Mechanical Expert, Crane Co., Chicago

NECROLOGY

HENRY G. STOTT

Henry Gordon Stott, superintendent of motive power of the Interborough Rapid Transit Company and New York Railways Company of New York, died at his home in New Rochelle, January 15, 1917, after an illness of many months.

He was a native of the Orkney Islands, Scotland, where he was born in 1866. After a thorough grounding in the fundamentals at the hands of his father and elementary school instructors, he was enrolled as a student at the Watson Collegiate School, Edinburgh. On leaving this institution he entered the College of Arts and Sciences at Glasgow, and began a course in mechanical engineering and electricity, graduating in 1885. In the year previous he had entered the employ of the Electric Illuminating Company of Glasgow. Shortly after graduating he was made assistant electrician on board

Henry G. Stott

the steamship *Minia,* belonging to the Anglo-American Telegraph Company. For the next four and one-half years he was engaged with those duties, during the course of which he saw much service in connection with repairs to the cable lines of that company. In this period he undertook a number of experiments that resulted in the introduction of improved methods of handling cable repairs. He was also identified with the "duplexing" of the United States Cable Company's main cable (2750 knots), the longest duplex cable in the world.

In 1889 Mr. Stott was made assistant engineer of the Brush Electric Engineering Company's plant at Bournemouth, England. The following year he was offered a post by Hammond & Co. as assistant engineer in the construction of an underground cable and power plant at Madrid, Spain. He remained there until 1891, when he came to the United States to install an underground cable and conduit system for the Buffalo Light and Power Company (now the Buffalo General Electric Company). This work was completed with a degree of success that reflected very greatly to the credit of Mr. Stott, and as a result he was named engineer of the company, and during the next ten years was one of the most active figures in the industrial progress of Buffalo. During this period he designed and executed some notable construction work, including a power plant on Wilkeson Street, Buffalo.

His work attracted wide attention and in 1901 he was appointed superintendent of motive power of the Interborough Rapid Transit Company, New York City, a position which he filled with signal success. At the time he took up these duties the Interborough had not yet been organized, the company having the title of the Manhattan Railway Company. The post which Mr. Stott was called to had just been created, and it devolved upon him to organize the operating force, in connection with which he completed the Seventy-fourth Street power plant of the company, various sub-stations and transmission lines.

When the Manhattan system was amalgamated with the Interborough, in 1904, Mr. Stott was invited to retain his office with the new corporation. He accepted and immediately took over supervision of the construction of the power plant on Fifty-ninth Street. Since that time he has been constantly in charge of design, construction and operation of the power-generating stations and the distributing system of the Interborough, which comprehends both the subway, elevated and surface lines of New York City.

The plans for the electric-power system of the new subway lines have been developed under his supervision and the construction has progressed so far and bears so strongly the stamp of his work that when completed it will be a monument to him.

Mr. Stott was a firm believer in coöperation among engineers through the agency of the engineering societies. He was elected president of the American Institute of Electrical Engineers for the term of 1907 to 1908. He was a manager of The American Society of Mechanical Engineers from 1907 to 1910, and from 1911 to 1912, and he was vice-president of the Society from 1912 to 1914. He was a director of the American Society of Civil Engineers in 1911, and was vice-president and a trustee of the United Engineering Society at the time of his death.

In the American Institute of Electrical Engineers he was a member of the Standards Committees, the Public Policy Committee, the Committee on Development of Water Power, the United States National Committee of the International Electrotechnical Commission, the Power Stations Committee, the Committee on Economics of Electric Service and the Edison Medal Committee. He was one of the Institute representatives on the Joint Committee on the Metric System, of which he was an ardent advocate.

In the Mechanical Engineers, he served on the Special Committee on Pipe Thread Gages in 1913 and 1914, as chairman of the Committee on Flanges and Pipe Fittings from 1912 to 1914, as chairman of the Conference Committee on Electrical Engineering Standards in 1913 and 1914. He was a member of the Executive Committee of the Council in 1913 and 1914, a member of the Advisory Committee of the Boiler Code Committee, and in 1916 was appointed a member of the Standardization Committee. He represented the Society on the Board of Trustees of the United Engineering Society.

As a result of his unusually wide experience and extended research, Mr. Stott was called upon often to contribute papers to the various engineering societies. He was especially well known for his minute analysis of engineering problems. Among the large number of papers which he has written on his subjects are The Conversion and Distribution of Received Currents, Power Plant Economics, Notes on the Cost of Power, Steam Pipe Covering and Its Relation to Station Economy, Tests of a 15,000 Kilowatt Steam Engine Turbine Unit, Power Plant Design and Operation (a series), etc.

Mr. Stott was a remarkable figure in the engineering world because he was in the front rank of both electrical and mechanical engineers; because in both branches of the art he was a master of theory and practice, and because with these technical qualifications he combined a rare executive ability and power of inspiring the confidence of his employees and of bringing out the best that was in the men who worked for him.

W. S. F.

AUGUSTUS W. COLWELL

Augustus W. Colwell, who died in New York on January 2, 1917, was a member of one of the oldest families of mechanics in New York, a pioneer in the manufacture of sugar machinery of the modern type, and a man who was associated in many ways in the engineering development of the country during the past fifty years. He was the oldest son of Lewis Colwell, founder of the Colwell Iron Works, who started in business for himself in 1840 in a small foundry on Charles Street, New York. Among the important undertakings of the Colwell Iron Works was the establishment as an adjunct of the main business a ship building yard in Jersey City, where several of the Civil War monitors were constructed and many vessels of the United States Navy were prepared.

Mr. Colwell was born in New York City on February 5, 1842, and educated in the public schools and in the College of the City of New York. In 1861 he was apprenticed in his father's machine shop and foundry, starting in the drawing room and later working in the foundry as a moulder. He afterwards was general superintendent of the plant and spent portions of each winter in Cuba inspecting the erection of the company's sugar machinery and attending to new orders. On the death of his father he purchased the interests of the other heirs and became president and owner of the Colwell Iron Works, until 1906, when he retired from business. By his numerous inventions and by leading in advanced engineering and foundry practice, he became prominent in English, French and Spanish-speaking America as a manufacturer of sugar machinery, and apparatus for the manufacture of other products requiring the use of evaporators, as well as steam engines, pumping engines, and miscellaneous machinery.

Under his supervision the first successful diffusion battery for handling sugar cane liquors was erected and operated at the Louisiana Experimental Station located on Governor Warmoth's Magnolia Plantation on the Lower Coast. He was among the first to design and manufacture machinery to use bone char for refining sugar and used it at the plantation for refining direct in one process. He was a pioneer in the use of water tube boilers on sugar plantations in which bagasse was used as fuel. He patented a bagasse burner for this purpose and installed plants using this fuel on plantations in Cuba. His system of returning all exhausts and drips to the boiler house and utilizing the exhaust steam for the vacuum pan and triple effect was much sought for by the planters.

He also was one of the first engineers to advocate clarifiers, steam trains and centrifugals to take the place of the old open kettle direct-fired as used by the earlier sugar makers. He remodeled many old style plants on sugar plantations by supplying centrifugals to eliminate the molasses from the magna after it left the vacuum pan. By contrast, the old cone moulds and banana leaf moulds which were common at that time had to be stored for weeks in dark cellars and allowed to drain in order to eliminate the molasses.

A great deal of interesting work was done by Mr. Colwell in fields totally different from those which engaged his chief attention. He patented and erected for New York City refuse crematories which were used by the late Colonel Waring when he was Commissioner of Street Cleaning. He did the steel and iron work for a number of lighthouses erected on the Atlantic and Gulf coasts. He made many experiments for the United States Government in the interest of the sorghum industry, designing and operating the machinery, and also furnished much machinery for the glucose trade. It is interesting to note that Lewis Colwell, his father, was the first to use coal in a cupola to melt iron, and that similarly he was the first, in New York City, to use coke in a cupola.

During the Civil War, in spite of the fact that the Colwell Iron Works were actively engaged in Government work, Mr. Colwell enlisted twice with the 137th New York Volunteers and was honorably discharged as Color Sergeant. About 1886 he was made Commander for the term of two years of the John A. Dix Post 135 of the Grand Army of the Republic.

Mr. Colwell was one of the charter members of The American Society of Mechanical Engineers and signed the register at the first Annual Meeting. During the past ten years he traveled extensively, once around the world, once to the Orient and once to South America. He is survived by four sons, all following the engineering profession, and by a daughter.

ALFRED C. EINSTEIN

Alfred C. Einstein was born in Hoboken, N. J., in 1866. He received his elementary education in the St. Louis Public Schools, later graduating from the Manual Training School. He began a course in Washington University, but left before its completion, to become manager of a mining property in Silver City, N. M., which position he held for several years.

In 1891, Mr. Einstein returned to St. Louis to become president of the Consolidated Engineering Co., and held this office until 1894. During that period he succeeded in building forty different plants, including waterworks, steam plants and electric- and street-railway plants.

Between the years 1894 and 1896, he was vice-president and manager of the Paducah Electric Light and Street Railway Co., of Paducah, Ky. He sold out his interest in this company in 1896 and returned to St. Louis, where he purchased the Suburban Electric Light and Power Co. He also organized the St. Louis County Gas Co.

In 1904, he sold the Suburban Electric Light & Power Co. to the North America Co., and in 1906 purchased the King Electric Light Co., which later was merged with the Suburban Electric Light and Power Co. In 1911 he became vice-president and general manager of the Union Electric Light and Power Co., which office he held at his death, November 20, 1916.

Mr. Einstein had always taken an active interest in the business and civic affairs of St. Louis. He was the fourth vice-president of the Business Men's League, and was largely instrumental in bringing many conventions to St. Louis. He became an Associate-Member of the Society in 1905.

THOMAS HATTERSLEY BELCHER

Thomas Hattersley Belcher was born in Newark, N. J., in December 1876. He was educated in the Newark High School and later in the technical and mechanical drawing schools. His early experience in mechanical work was obtained while in the employ of Cyrus Currier & Sons, Newark, N. J. In 1900 he affiliated with A. & F. Brown Co., as engineer and superintendent of installations of power transmission equipment in manufacturing plants. In 1904 he became assistant chief engineer of that concern. Between 1906 and 1913 he was with the Chicago Coated Board Co. as general mechanical superintendent. In May 1913 he became engineer and representative for the Black-Clawson Co., Hamilton, O., resigning after two years, to become manager of the Carthage Machine Co., of Carthage, N. Y. His death occurred Nov. 7, 1916, while acting in this capacity. He became a Member of the Society in 1913.

FREDERICK W. HOLMGREN

Frederick W. Holmgren was born December 29, 1891, in Brooklyn, and died there December 29, 1916. He received his early education in the Brooklyn Public Schools and attended Manual Training High School for a time. After leaving school, he took an evening course at the Brooklyn Polytechnic Institute, working in the projectile department of the E. W. Bliss Co., Brooklyn, during the day. He received his degree of Mechanical Engineer from that institution in June, 1914. He remained with E. W. Bliss Co. for a time after his graduation, resigning to enter into partnership with the Berggren & Pearson Machine Co. of New York, with which concern he was affiliated at the time of his death. He was elected to Junior Membership in the Society in November, 1915.

NAPOLEON DuBRUL

Napoleon DuBrul was born in Montreal, Canada, on June 22, 1846, and died in Cincinnati, October 23, 1916. At the age of fourteen, he became apprentice in the Gilbert Machine Shop. In 1866 he went to Chicago where he invented the tin cigar mold and later the tin-lined wooden cigar mold. He removed to Cincinnati in 1872 and in 1879 became a member of the firm of Miller, DuBrul & Peters Mfg. Co. In 1893 the members of the firm bought and reorganized the Anniston Pipe and Foundry Co., of Anniston, Ala., which was later consolidated with the American Pipe & Foundry Co. of Chattanooga, Tenn., and in turn was sold to the U. S. Cast Iron Pipe & Foundry Co.

Mr. DuBrul devoted his inventive skill to the development of machinery for making cigar molds. He designed, patented and marketed many different machines and appliances used in the cigar business in all countries of the world.

He became a Member of the Society in 1900 and was a member of the Business Men's Club and the Queen Club of Cincinnati.

WILLIAM L'E. MAHON

William L'E. Mahon was born in Detroit, Mich., June 19, 1861. His education was secured at the University of Michigan, succeeded by a course at the Massachusetts Institute of Technology. He specialized in marine-engine-construction work, beginning as an apprentice in the Dry Dock Engine Works in Detroit, and being later engaged as mechanical engineer and chief draftsman with the Frontier Iron & Brass Works, later acting as assistant superintendent on construction of heavy marine engines with the same works, and subsequently with the Brown Hoisting Machinery Company of Cleveland, O., with which company he continued several years.

Mr. Mahon was also connected several years with the New York office of Taylor Wharton Iron & Steel Company, of High Bridge, N. J., later representing them in the Pacific Northwest. It was while engaged in work with the last-named company, with headquarters at Butte, Montana, that he died, October 6, 1916, at Ogden, Utah.

Mr. Mahon was a member of the Technology Club of New York and became a member of this Society in May, 1889.

AMONG THE SECTIONS

DURING the month just closed, President Hollis has visited the Sections at Detroit, Chicago, Milwaukee, New Orleans, Birmingham and Atlanta, also the Student Branches at Purdue University and the Georgia School of Technology. In his tour of these Sections and Branches, President Hollis spoke in addition at the Cleveland Chamber of Commerce and the Detroit Chamber of Commerce, and addressed the students at Tulane University. Dr. Hollis' message to these Sections and Branches is published below, embodied in the reports of the meetings which he addressed.

Our two new sections, at Erie and Indianapolis respectively, both report progress in their plans of activities. At Indianapolis an Engineers Club is being organized and this will be an affiliation of the several local engineering organizations, including our own Section. At Erie, the new Section is putting into effect plans for securing a substantial membership. This Section will work in close coöperation with the existing local engineers' society, the Engineers Society of Western Pennsylvania, and a committee consisting of R. F. Benzinger, chairman, H. N. Dodge and F. P. Klund, has been appointed to work out the exact relations between our Section and the local society.

The New Year has brought the Providence Engineering Society a long and varied monthly program. The society is to be congratulated on its endeavor to make this year a banner year for the engineering profession in Rhode Island. No less than five meetings of the society were held in January, at two of which new sections, a Power Section and a Municipal Highway and Water Supply Section, were formed.

SECTION MEETINGS

BALTIMORE, DECEMBER 13

At a meeting of the Baltimore Section on December 13, 1916, a report of the committee handling the organization of the Associated Technical Societies was considered. This association is to consist of eight branches of national societies in Baltimore and other societies duly elected by the Board of Governors. Its purposes are to advance the interests of all technical organizations through coöperation, to promote goodwill and fellowship between the members of the various societies and to present for discussion and action, subjects of common interest, thereby strengthening the influence of technical men in matters of public welfare. The governing board will consist of the presidents of the member organizations. The individual sections will continue

to hold their separate meetings as heretofore, but members of any member section will be privileged to attend meetings of any other member section as guests. F. M. Chatard was appointed fifth member of the executive committee and H. Garner, A. Kennedy and E. B. Passano were appointed a meetings committee.

During the latter part of the evening Captain F. H. Wagner gave an address on the Recovery and Use of By-Products from Coal Tar. He illustrated the various processes of gas manufacture and by-product recovery and outlined the production of intermediates and final products. He described what had been done in this country in the development of benzol plants, aniline dye plants and plants for the production of explosives, illustrating by slides the apparatus and processes. At the close of the lecture American coal tar by-products were exhibited.

A. G. Christie,
Section Secretary.

BUFFALO, JANUARY 3

On January 3, 1917, over two hundred and fifty engineers, mechanical, electrical, civil, motor-car and others, celebrated the first convivial night of the Buffalo Engineering Society, and made merry until well after midnight.

Paul Wright,
Section Secretary.

BUFFALO, JANUARY 17

Highway Bridges was the subject of Chas. M. Spofford's address before the Engineering Society of Buffalo on January 17, 1917. He told of the great opportunity for engineers in the matter of standardization of the width of all bridges to be built, and quoted figures which proved that the increase in highway traffic during the last few years called for wider bridges. Relative to Buffalo's condemnation of several viaducts because of the effect of corrosion upon the floor supports, he claimed this was caused mostly by the forming of gas pockets in the understructures of railroad bridges. By means of lantern slides, Mr. Spofford showed various types of bridges, analyzing each design and describing various types of wearing surfaces and supports for wearing surfaces and the distribution of loads.

Frank D. Jackson, engineer of bridges and viaducts of Buffalo, followed Mr. Spofford with some of his experiences with bridges. He too advocated smooth understructures so as to eliminate gas pockets, stating that Buffalo had practically eliminated corrosion by applying red lead, sand and cement to the understructures of street viaducts.

Louis J. Foley,
Assistant to Secretary.

CHICAGO, JANUARY 5

Dr. Hollis addressed the Chicago Section at their meeting January 5, 1917, on the status of the engineer and his relation to society. His plea was for the recognition of engineering as a learned profession on an equality with medicine, law and theology. He outlined the difference between the various professions in their relation to the welfare of society. To him engineering is a constructive profession working for the welfare of humanity. He cited Eli Whitney and James Watt as instances where the work of individual men had changed the entire aspect of social and business life. Well's dictum "The history of humanity is the history of man's attainment to external power." he intepreted in the sense that the history of mankind is the history of invention, and invention is at bottom the practical expression of man's desire to benefit his fellow men.

Dr. Hollis concluded his remarks by outlining the relations that should exist betweeen the various local Sections of the Am.Soc. M.E. and other existing organizations of engineers in the same locality. He encouraged closer relations between such groups of engineers and held that the ultimate good of engineering demanded the closest coöperation of such organizations.

Robert E. Thayer,
Section Secretary.

CINCINNATI, DECEMBER 21

The Concrete Bridges and Viaducts of Cincinnati was the subject of the paper by Frank L. Raschig at a joint meeting of the Cincinnati Section and the Engineers' Club of Cincinnati, December 21, 1916. In outlining the activity of Cincinnati in the way of bridge and viaduct building, the speaker stated that since 1910 the city has expended about $2,000,000 for concrete bridges and viaducts. Four viaducts and fifteen bridges of lesser importance have been built and thirty small concrete bridges have replaced wooden structures. It is the settled policy of the Engineering Department of the city to build only concrete bridges and viaducts in the future, unless absolutely impracticable.

The Gilbert Avenue viaduct consists of 30-ft. spans of column, beam and slab construction, the entire structure supported on concrete piles. The structure is about 1200 ft. long and 80 ft. wide, with roadway 58 ft. wide. It cost, exclusive of property, $240,000 or about $2.40 per sq. ft. The main portion of the Ludlow Avenue viaduct consists of six solid barrel arches of 85-ft clear span built on a skew of 52 deg. with a roadway of column, beam and slab construction over these arches. The approaches leading up to these arches are of column and beam construction of 24-ft. spans. Length 1300 ft., width 60 ft. with 40 ft. of roadway, cost about $280,000 or $3 per sq. ft. The Hopple Street viaduct consists of a series of balanced cantilever beams arched in shape. A pier and the cantilever arms on each side compose a unit, the arms being balanced for dead load and for full live load. Length 1000 ft., width 60 ft. with 46 ft. roadway, cost about $450,000 or $3.75 per sq ft. An arch of 180-ft. span and consisting of three ribs, forms the main portion of the Park Avenue viaduct. The approaches are of column, beam and slab types with spans of 25 ft.

Mr. Raschig concluded his paper by stating that Cincinnati is planning to replace a certain number of wooden and steel structures each year so as to have finally none but concrete bridges

John T. Faig,
Section Secretary.

DETROIT, JANUARY 3

The first meeting of the Detroit Section was held on January 3, at the Board of Commerce, after a dinner given in honor of President Ira N. Hollis, at which over seventy engineers were present. Members of the local sections of the other national engineering societies and of the Detroit Engineering Society were invited to be present to greet Dr. Hollis and to hear him speak on the scope, purpose and opportunities of the local section.

Dean Mortimer E. Cooley, of the engineering department of the University of Michigan and president of the Section, presided. Before the address of Dr. Hollis, Dean Cooley called on several Detroit engineers for short talks. Those who spoke were Theodore A. Leisen, president of the local section of the American Society of Civil Engineers; A. A. Meyer, president of the local section of the American Institute of Electrical Engineers; Horace Lane, president of the Detroit Engineering Society; Clarence W. Hubbell, City Engineer, and Walter S. Russel of the Russel Wheel and Foundry Company.

Dr. Hollis took for the topic of his address the opening sentence of H. G. Wells' novel, The World Set Free—"The history of mankind is the history of the attainment of external power." He traced the development of machinery from the crude club wielded by the savage through the wheelbarrow, plow, steam engine, down to our present day complex machinery; and emphasized the fact that the progress made has always been toward the betterment of the condition of humanity. He stated that the engineer in his work sees not only the material outline of his machine as he works upon it, but sees back of his machine the relation it shares in the elimination of drudgery; and that the engineer in building his machine is like the painter in painting his picture who puts upon his canvas something besides a mere picture. "When I look at a copy of Millet's painting, the Angelus," said Dr. Hollis, "I see portrayed in the picture something of the struggle of humanity against nature and adverse conditions, something of the apparent futility of life in the face of eternity.

"Realizing the importance of their profession to all humanity, the engineers should make more of the esthetic aspects it presents. They should ever be willing in the public service. In their own ranks they should have complete organization for mutual benefit and to advance the condition of humanity by the efficiency among engineering men such organization should increase."

J. W. Parker,
Section Secretary.

INDIANAPOLIS, JANUARY 19

A joint meeting of the Indianapolis Section was held at Lafayette on Friday afternoon, January 19, in connection with the annual meeting of the Indianapolis Engineering Society and the Indianapolis-Lafayette section of the American Institute of Electrical Engineers.

The speaker provided by the Indianapolis Section of our Society was Harrington Emerson, Mem.Am.Soc.M.E., of New York, whose subject was Flow Values Through a Manufacturing Plant. This paper was illustrated by slides and covered Mr. Emerson's conception of the organization of a typical manufacturing industry in its financial aspect from the time of the assembly of the capital investment to the distribution.

The discussion of this topic by Mr. Emerson was as thorough and informing as would be expected by those who are more or less familiar with his expert services in the efficient organization of industries.

W. H. Insley,
Section Chairman.

MILWAUKEE, JANUARY 9

Dr. Ira N. Hollis, President Am.Soc.M.E., addressed the Milwaukee Section at their meeting, January 6, 1917, his subject being The Place of the Engineer and the Engineering Society in Modern Life.

Fred. H. Dorner,
Section Secretary.

NEW YORK, JANUARY 9

In line with the previous meetings of the season, the subject for the January 9, 1917, meeting was Industrial Preparedness in its Relation to Navy Yard Administration. The speaker, Commander E. P. Jessop, U. S. N., pointed out that provision has been made for those engineers beyond military age or otherwise disqualified to take up arms, to enroll for service at the navy yards in time of emergency and thereby release for sea duty the regular naval officers.

Departing somewhat from the announced topic, Commander Jessop proceeded to point out the citizen's obligations to his country and the vital necessity of every individual having his work mapped out beforehand because when trouble comes it usually comes at short notice. Scouting the idea that preparedness leads to militarism, he gave France as an example of democracy where individual liberty has not been marred by military training. England, who before the war was very much like ourselves, has taken two years to awaken to a realization of the situation and the British citizen is now fully alive to his obligations.

By way of showing some of the activities of the Navy Commander Jessop gave a most interesting account, illustrated with slides, of the trip of the *U. S. S. Tennessee* to Europe at the outbreak of the war for the purpose of succoring refugees. He followed with views of the same ship when on a voyage to South American ports and showed finally the destruction of the ship in the harbor of Santo Domingo.

An informal discussion in which attention was directed to the need of more men to handle the new ships of the Navy, closed the meeting.

Alfred D. Blake,
Section Secretary.

PHILADELPHIA, DECEMBER 14

A joint meeting of the Philadelphia Section and The Franklin Institute was held December 14, 1916. Prof. Carl C. Thomas, Mem.Am.Soc.M.E., of Johns Hopkins University delivered an illustrated lecture on The Cooling of Water for Power Plant Purposes. He briefly reviewed the methods of cooling water, making special reference to efficiencies obtained by spray ponds. He described a new form of spray head and reported upon tests made under widely varied conditions. An interesting discussion followed which dealt with factors affecting the efficiencies of spray ponds.

W. R. Jones,
Section Secretary.

PROVIDENCE, DECEMBER 27

At the meeting of the Providence Engineering Society, Prof. Frederick H. Newell, Mem.Am.Soc.M.E., addressed the society on the work of the United States reclamation service in the far West. He illustrated his address by colored slides, explaining the engineering features of the Roosevelt, Elephant Butte and Arrowrock dams, their tunnels and the Gunnison River tunnel. The pictures also showed views of the new homes built on the irrigated land and, for comparison, the same country when it was the home of the Indian and the cowboy.

Albert E. Thornley,
Corresponding Secretary.

ST. LOUIS, DECEMBER 3

At a dinner given on December 3 by the St. Louis Section, Prof. Franklin Gephart gave a very interesting talk on Some Economic Aspects in Relation to the High Cost of Living. His talk was followed by discussions from a number of the members.

L. A. Day,
Section Secretary.

STUDENT BRANCHES

ARMOUR INSTITUTE OF TECHNOLOGY

At the meeting of the Student Branch of Armour Institute of Technology held December 6, 1916, interesting and instructive talks were given by several members of the Branch. The first subject presented was The Different Types of Automobile Engine Lubrication by L. A. King, followed by an explanation of the lubrication of the spring shackles on the new model of the Marmon automobile. R. A. Morse spoke next on the Manufacture of Water Gas, explaining the steps in the manufacture of the gas in a modern plant. The last speaker was Mr. Bretting whose subject was The Construction of Stacks.

E. W. Haines,
Branch Secretary.

BUCKNELL UNIVERSITY

The first meeting of the present school year of the Student Branch of Bucknell University was open to all who would attend. The purpose and workings of the branch were explained, and all who were not members were urged to ally themselves with it as early in their course as possible.

F. E. Burpee,
Branch Correspondent.

BUCKNELL UNIVERSITY

The regular meeting of the Bucknell University Student Branch was held December 11, 1916, when C. M. Kriner gave a talk on Jigs and their Application in Modern Machine Shops, illustrative of the simple type of jig as used for plain drilling and reaming, and the more complex type used in performing a number of operations on the work it holds. Mr. Weaver joined in the discussion.

During Thanksgiving vacation ten members of the Student Branch, accompanied by Prof. Frank E. Burpee, Mem.Am.Soc. M.E. and Prof. Taylor, made a six-day inspection tour to York, Lancaster, Philadelphia, Trenton and Wilkes-Barre, visiting various factories of mechanical interest. It was the most successful trip the Branch has taken during its history, and plans are on foot for conducting several of these tours each year.

J. A. Case addressed the Student Branch of Bucknell University at their meeting on January 8, 1917, on the Reservoir and Filtration Plant for the Jersey City Water Supply. He furnished some views of the reservoir and explained, by means of a blackboard sketch, the method of filtering and testing water for the percentages of the various kinds of bacteria.

C. M. Kriner,
Branch Secretary.

CARNEGIE INSTITUTE OF TECHNOLOGY

The Student Branch of the Carnegie Institute of Technology held its regular meeting November 15, 1916. Mr. Frederick Parke, Mem.Am.Soc.M.E., gave an interesting illustrated lecture on Brak-

ing, showing the development of brakes from their primitive type to the latest Westinghouse air brake used on the railroads of the country today. He also showed the tabulated results of many tests made on various railroads throughout the United States and pointed out that the development of the railroads followed very closely the development of the air brake, since the capacity of the brake determines to a large extent the permissible speed and weight of the equipment.

On December 13, 1916, the Branch heard a most interesting address by Lieut. J. B. Oldendorf, U.S.N., on Mechanical Engineering in the Navy. The speaker explained the considerations determining the design of various types of naval vessels and described in detail the installation of power plants abroad, battleships, cruisers, torpedo boats, destroyers and colliers. He indicated the design and arrangement of boilers, engines, turbines, pumps, etc., on naval vessels and gave his opinion that the internal-combustion engine of the oil-burning type is the marine engine of the future. He cited the successes experienced with this type of engine in submarines.

More than an hour of inquiries, questions and remarks on the part of the students evidenced the interest of the members of the Branch in the discussion which followed. The meeting closed with Lieutenant Oldendorf's recounting, on request, many interesting and amusing incidents experienced during his first cruise.

J. H. Davis,
Branch Secretary.

CASE SCHOOL OF APPLIED SCIENCE

The Value of the Engineer to the Community was the subject of the address of C. E. Drayer, Secretary Cleveland Engineering Society, before the Student Branch of the Case School of Applied Science on January 10, 1917. He emphasized the present-day need of engineers in the management of municipal affairs, citing the fire and building laws, street railways, water plants and power stations as instances where the skill and knowledge of the engineer should be employed. He showed by lantern slides a few newspaper columns on the value of the engineer to the community, explaining that the newspaper was the medium used by the Cleveland Engineering Society for bringing the relation of science and public affairs before the people.

Alex. Treuhaft,
Branch Secretary.

COLORADO AGRICULTURAL COLLEGE

At a meeting of the University of Colorado Student Branch, held November 27, 1916, Mr. Gorton gave a comprehensive talk regarding the measurement of steam by means of the orifice, U-tube and Ledoux bell type of meters.

E. C. Johnson,
Branch Secretary.

COLUMBIA UNIVERSITY

The Student Branch of Columbia University reports the successful carrying out of its project of uniting the Chemical, Civil, Electrical and Mechanical engineers under a joint governing board. The officers of the Branch are John L. Kretzmer, president; William M. Henry, vice-president; R. W. Thompson, secretary and E. H. Shea, treasurer.

John L. Kretzmer,
Branch President.

CORNELL UNIVERSITY

The Cornell University Student Branch began the new year with a very interesting meeting on January 13, 1917. The speaker of the evening was Prof. Dexter S. Kimball, Mem.Am. Soc.M.E., who gave an instructive address on the problems of the practicing engineer. He described some of the difficulties and stumbling blocks of young engineers, giving his personal experiences as a designer and consulting engineer.

S. M. Barr,
Branch Secretary.

COLUMBIA UNIVERSITY

The various engineering societies on the campus of Columbia University have been consolidated into an organization called the United Engineering Societies, which is controlled by a governing board composed of two delegates of each branch society. This consolidation was the outcome of a conference between the chairman and honorary chairman of the Student Branch of the Am.Soc.M.E. The Chemical Society was formed as a result of this consolidation and the Mining Society is expected to enter the organization shortly. The chairman of the Mechanical Society was elected chairman of the governing board.

The first meeting of the newly organized society took place December 14, 1916, and was in the form of a smoker which proved most successful. The speakers were Calvin W. Rice, Secretary Am.Soc.M.E., H. H. Norris, Charles Butters and Herman A. Metz.

John L. Kretzmer,
Branch Chairman.

LEHIGH UNIVERSITY

On December 14, 1916, an interesting meeting was held by the Student Branch of Lehigh University, which the Civil Engineers also attended.

Prof. Frank P. McKibben, head of the Civil Engineering Department of the University, spoke on the Hill-to-Hill Bridge to be erected between the Bethlehems. He covered the history of the means of transportation across the river and outlined the way in which the subject of a new bridge was taken up. He told how he had planned this new bridge and exhibited several of the first plans as well as the plans for the finished structure which, when completed, will be over a mile in length and will be Y-shaped, allowing for all traffic on both sides of the river. He estimated the cost to be about \$1,000,000, most of which has already been pledged, so that the construction of the bridge is practically assured.

F. L. Benscote gave a comprehensive talk on Mechanical Refrigeration. He described the two types of refrigerating plants, the absorption and compression types, the latter of which is in more common use. By means of numerous blackboard sketches, he explained in detail the operation of the two types and the manufacture of artificial ice.

F. M. Porter,
Branch Secretary.

POLYTECHNIC INSTITUTE OF BROOKLYN

The Polytechnic Institute of Brooklyn held a meeting January 6, 1917 when The Development of Poppet Valve Uniflow Engines and their Status in the United States was discussed by Siegfried Rosenzweig, Mem.Am.Soc.M.E. He traced the development of the poppet valve uniflow engine from its origin to the present-day engines of Lenz and Stumpf. He gave as the reason for its great success, its non-destructibility under high pressure and high temperature, in which two phases it approaches in efficiency the explosion engine. Mr. Rosenzweig further favors it because there is no wear or rubbing and hence very little lubrication. He has endeavored to have locomotive manufacturers introduce these engines in their locomotives, but due to the fact that the concerns are busy manufacturing war implements, he has received very little encouragement.

The Institute has elected two men to represent the Society in editing the Engineer, their technical publication.

George Cherr,
Branch Secretary.

PURDUE UNIVERSITY

The Student Branch of Purdue University, at its meeting on December 16, 1916, was addressed by Dean C. H. Benjamin, Vice-President Am.Soc.M.E., of the Engineering School of the University, on the Thirty-Seventh Annual Meeting of the Society. His talk was general, giving a description of the Engineering Societies Building, the program which was carried out at the meeting and the method of presenting and discussing papers. He emphasized, as the great advantage of attending these conventions, the opportunity of meeting men, exchanging experiences and gathering pointers.

Geo. A. Ruess,
Branch Corresponding Secretary.

PURDUE UNIVERSITY

Dr. Ira N. Hollis, President Am.Soc.M.E., addressed the Student Branch of Purdue University on January 8, 1917. The basis of Dr. Hollis' talk was the title of H. G. Wells' book A World Set Free and he defined the engineer's responsibility for the "setting free." He especially emphasized the part played by James Watt in his improvement of the steam engine. Dr. Hollis ridiculed the idea of narrowness associated by many with the engineer and took issue with the writer of the statement that there is no romance connected with a machine. He claimed that the beauty of an engine is as real as the beauty of a picture for it is the "picture behind the picture" that makes a picture either famous or commonplace. Referring to Millet's Angelus, Dr. Hollis said that the human strife presented there would undoubtedly be present if the figures were replaced by broken machinery.

G. A. Reuss,
Branch Secretary.

THROOP COLLEGE OF TECHNOLOGY

On November 20, 1916, the Student Branch of Throop College of Technology conducted a meeting of the student body and faculty of the college, at which Charles V. Knight, inventor of the sleeve-valve motor, gave an instructive talk on the early development and mechanical features of his invention. Mr. Knight used a cut-away Stearns motor to illustrate the mechanism and operation of his motor.

Reginald Coles,
Branch Secretary.

UNIVERSITY OF ILLINOIS

Dr. Ira N. Hollis, President Am.Soc.M.E., spent a part of Tuesday and Wednesday, January 9 and 10, at the University of Illinois, where he was the guest of Past-President W. F. M. Goss. Dr. Hollis was the guest of honor at a dinner tendered him by the Dean and heads of departments of the College of Engineering, where the president, vice-president and members of the council of the university, the local members and the president of the Student Branch of the Am.Soc.M.E., were also guests.

In Dr. Hollis' address before the Student Branch, he aimed to impress upon the young men the dignity of their calling and the significance of the engineer as a factor in the social, political and economic progress of the nation.

W. F. M. Goss,
Branch Correspondent.

UNIVERSITY OF NEBRASKA

At the November, 1916, meeting of the Student Branch of the University of Nebraska, M. F. Clark gave an address on the Relation of the Engineer to National Preparedness, presenting the questions involved and some of the views expressed by the most prominent engineers on this subject. Foundry Practice was discussed by Mr. Smith, instructor at the University in that branch of work. He was followed by Prof. J. D. Hoffman, Mem.Am.Soc.M.E., who spoke on the Chicago Edison Plant, reviewing Mr. Insull's paper in The Journal, November, 1916, on that plant and adding his own observations from a personal inspection of the plant.

Orlo A. Powell,
Branch Secretary.

UNIVERSITY OF MISSOURI

The Relations of the Student Branch to the Society and the advantages realized by taking an active part in the Society, were discussed by Prof. H. W. Hibbard, Mem.Am.Soc.M.E., at the first regular meeting of the Student Branch of the University of Missouri, held October 26, followed by an illustrated lecture by D. E. Foster, Associate Professor in Mechanical Engineering, on Air Compressors and their various uses.

Louis Seuter was elected chairman for the year 1916-1917; B. W. Coots was elected treasurer and recording secretary, and C. N. Johns was elected corresponding secretary.

At the second meeting of the Branch, held November 9, M. H. Brigham, Assistant in Manual Arts, gave an interesting talk on Shop Practice, laying special stress on the production of machinery.

C. N. Johns,
Branch Secretary.

VIRGINIA POLYTECHNIC INSTITUTE

On December 8, 1916, the Student Branch of Virginia Polytechnic Institute held an interesting meeting, at which Frank B. Gilbreth, Mem.Am.Soc.M.E., gave a talk on Motion Study as a means of increasing the efficiency of operators and workmen in various occupations. Mr. Gilbreth cited several instructive instances of his observations for practical application of his method of corrected motions.

The method by which Mr. Gilbreth's observations are made is that of taking moving pictures of the operator at his work. In the background of the picture, a screen resembling a sheet of coördinate paper is placed; a light attached to the operator's hand traces a line across the screen; the graph thus obtained is studied and a wire model of the curve is made. By means of this model the shortest distance in which the space may be traversed is determined, and by instructing the operator to adopt motions in accordance with the corrected motions, his efficiency is many times increased.

By following Mr. Gilbreth's methods, three typists won the first and second international, and the first national speed prizes, and the golfers Nichols and Ouimet derived considerable benefit in their work.

G. E. Parker,
Branch Secretary.

WORCESTER POLYTECHNIC INSTITUTE

On January 5 1917, the Worcester Polytechnic Student Branch held a joint meeting with the student branches of the American Institute of Electrical Engineers and the Civil Engineers Society. The subject of the day was From Ore to Finished Pipe, by H. T. Miller, of Boston, who illustrated his lecture with motion pictures.

H. P. Fairfield,
Branch Secretary.

Am.Soc.M.E. Year Book, 1917

The new Year Book of the Am.Soc.M.E. is off the press and will be issued early in February. The volume contains general information regarding the Society, its objects and activities, calendar of events for 1917, the personnel of the Officers, Council and Committees for the year, together with the alphabetical and geographical lists of members of the Society, corrected to January 1, 1917. A list of past officers and a calendar of all general meetings since the first meeting in 1880, a list of depositories for Transactions, also the Charter and By-Laws of the Society are included in addition for reference.

The alphabetical list of members occupies 302 pages and contains 7,704 names. This is an increase of 773 over last year. The geographical list extends over 170 pages.

Attention is called to the scheme of the alphabetical and geographical lists. In the alphabetical list are given the grade of membership in the Society, the title and business connections, the business and residence addresses. In the geographical list are given under each city or town, the names and business connections of members; experience has shown that this is the information most likely to be required from this list.

Every member of the Society receives a copy of this Year Book, bound in cloth. The geographical list of members is also issued as a separate publication, bound in paper.

EMPLOYMENT BULLETIN

THE SECRETARY considers it a special obligation and pleasant duty to make the office of the Society the medium for assisting members to secure positions, by putting them in touch with special opportunities for which their training and experience qualify them, and for helping any-one desiring engineering services. The Society acts only as a clearing house in these matters.

POSITIONS AVAILABLE

In forwarding applications, stamps should be enclosed for transmittal to advertisers; applications from non-members should be accompanied by a letter of reference or introduction from a member, such reference letter to be filed with the Society. Copy for notices must be in hand by the 15th of the month.

ASSISTANT CHIEF ENGINEER. Young man who has had experience in or made special study of power plant operation, to assist in running woodworking factory of 1000 hp. Knowledge of design of exhaust steam-heating on large scale desirable. Answer, stating age, past positions and salary expected. 83

DRAFTSMAN experienced in design of heavy machinery, rolling mills, etc. Location Connecticut. 98

YOUNG ENGINEER DESIGNER with technical education and special training in the design of automatic machinery for the manufacture of small interchangeable parts; excellent chance for advancement to one who displays ability and application. Location Chicago. 139

RECENT GRADUATES in mechanical engineering from schools of recognized standing desired for testing work in large steam-operated electric power plants. Preference will be given to applicants with experience in testing work and those now located in and around New York. Answer stating particulars of education, experience and salary desired. 167

TOOL DESIGNER who is resourceful and can follow work through to completion. Technical man with practical shop experience. Salary $25 to $35 per week according to ability. Location Connecticut. 185

SALES ENGINEERS, young men, between ages of 25 and 30 years, of good appearance, graduates of some approved engineering college, preferably M.E. degree. Applicant would be expected to undergo a period of probation and training in the various offices of company before being given more responsible and higher positions in sales work. Apply by letter in own handwriting, stating age, education, previous business training, if any, salary desired, etc. Location New York. 205

DESIGNER for special machinery and labor-saving devices, capable of following work through shop to completion. Location New York State. 248

SALES ENGINEERS or AGENCY on commission for one who is handling other lines, desired for the following territories: Tennessee, North Carolina, Minnesota, North and South Dakota. Past record must show familiarity with boiler plant practice. 433.

WORKS MANAGER, unusual opportunity for right man, 35-45; must be graduate engineer and have thoroughly demonstrated ability as machine designer and production man. Good organizer and hustler, preferably with ability to invest $5,000 at the end of 3 months if satisfactory. State fully education, experience, age, etc. Correspondence strictly confidential. 642

DRAFTSMEN. Experienced mechanical draftsmen, preferably not over 30 years of age. Permanent employment and advancement to capable men. Location New York State. 751

POWER ENGINEER for large industrial corporation operating its own steam and electrical power plants; young man with executive ability, mechanical or electrical engineering graduate, experienced in power plant and power distribution, design and operation. State age, school, year of graduation, detailed experience and salary expected. Location Michigan. 763

ENGINEER, experienced in manufacture of interchangeable parts, with thorough knowledge of die and tool design. Location New York. 764

DRAFTSMAN, familiar with power house work, such as the installation of its equipment, piping, etc., competent to work out the different problems involved. Salary $25 to $28 per week. Location New York. 769

SHOP INSPECTOR, over 30 years of age, competent to take charge of factory of 500 men, manufacturing large quantities of varied equipment; to represent New York office. Salary according to man. Location Massillon, Ohio. 770

ENGINEER skilled in handling of materials, to study the handling of materials at plants of large industrial corporation; experience with conveying machinery and other mechanical means of handling transporting materials. 782

HEATING AND VENTILATING ENGINEER to study heating and ventilation and various similar problems at plant of large industrial corporation. 783

CONSTRUCTION SUPERINTENDENT for contracting company engaged principally in municipal contracting. Applicant must be capable of handling men in water works and sewer construction and able to take a financial interest in the company. Location Middle West. 784

YOUNG ENGINEER to keep up machinery and design improvements and attachments for machines now running and design new machines as thought desirable. First work will be to assist in giving lines and positions of building construction now under way. Position will pay $40 per week to start, and as soon as results are obtained a responsible position with adequate compensation will be established. Location New York State. 785.

MECHANICAL ENGINEER who would be interested in partnership in established business dealing largely in apparatus pertaining to economical production of steam, as recording instruments, steam meters, water meters, calorimeters for fuels and gases, etc. Location New York. 736

SALES ENGINEER with experience, for Chicago Branch Office of concern manufacturing power-plant specialties, high-grade valves, jet apparatus, condensers, sprays, heat-transmission apparatus, oil-firing equipment, etc. Give full particulars and references. 793

DESIGNER on fittings and valves. Good draftsman with executive ability, capable of taking charge, but willing to work. Answer stating age, education, salary expected, previous positions and references. Location New York State. 794

ENGINEER familiar with application of handling equipment in general factory work. 795

DRAFTSMAN on boiler and stoker work. Two or three years' experience. Location New York. 797

ASSISTANT PROFESSOR OF MECHANICAL ENGINEERING, with five or more years' practice in gas or steam engineering design or construction and teaching experience, for technical institution. Position open now or in September, 1917. Location Pennsylvania. 798

STAFF ENGINEERS, experienced in manufacturing efficiency work, especially in routing, motion-study, time-study, rate-setting and introduction of bonus systems. Salary $150 per month. Location Chicago. 799.

YOUNG ENGINEER to assist in installing Gantt system in light industry employing both men and women. Prefer man who has had experience along this line. Location Georgia. 800

DRAFTSMEN familiar with power-plant design, piping layouts, foundation work, light structural-steel work and timber-platform construction, especially with experience in the design, of chemical plant equipment. Location Brooklyn. 803

MACHINERY DESIGNER to take charge of drafting force. Must have good and extensive experience in building machines for working sheet metals, as presses, shears, etc. Salary $225 to $250 per month. Location, Buffalo, New York. 804

DESIGNER on heavy machine tools and similar machinery. Good opportunity for high-grade designer with chiefly drawing-office experience. Location Pennsylvania. 40

ASSISTANTS TO CONSULTING ENGINEER, recent graduates from high-grade engineering school. Personality and correct use of English as

essential is technical training. Moderate salary with advancement. Answer in own handwriting with complete record of training. Location Ohio. 805

MEN AVAILABLE

Only members of the Society are listed in the published notices in this section. Copy for notices should be in hand by the 15th of the month, and the form of the notice should be such that the initial words indicate the classification. Notices are not repeated in consecutive issues.

RECENT TECHNICAL GRADUATE, now employed, desires to change position to one in which there is good opportunity for advancement. B-49

TECHNICAL GRADUATE, in charge of erection and design of plant and equipment for large chemical concern, wishes to change. Energetic, can purchase equipment to good advantage and install it to most economical utilization of floor space. Familiar with mechanical methods of storing and handling material. Available on reasonable notice. Salary $2100. B-50

MANAGER or SUPERINTENDENT where ability can be demonstrated and where there is an opportunity for advancement. Associate-Member; graduate mechanical engineer. Three years mechanical engineer of large steel company; two and one-half years chief engineer of electric company; two years in consulting engineering profession. Best references furnished. B-51

MECHANICAL ENGINEER with extensive acquaintance in Eastern territory would like to represent manufacturers who desire to increase their sales in the East on purely commission basis, or would form partnership with established firm of manufacturers' agents. At present employed. Salary $5000 to $10,000. B-52

ENGINEER-SALESMAN for concern desiring new business or development of special department. Capable of approaching with confidence architects and engineers or owners on larger construction operations in New York or New England and nearby states. B-53

NEW YORK SALES MANAGER, age 33, wants position with company capable of turning out special machinery, principally sugar machinery. Long experience and large clientele. B-54

WESTERN REPRESENTATIVE. Member, practical machinist, Stevens graduate. Age 36, married. Easterner with residence of ten years in the West. Engineering business and buying experience. Now employed by mechanical engineering contracting concern. Desires change and solicits position as Pacific Coast representative of Eastern manufacturer. Salary and commission basis. Would consider two non-conflicting lines. References. B-55

INSTRUCTOR or DIRECTOR. Member. Technical education and over twenty years' practical experience. At present superintendent of industrial school. Desires position in vocational or industrial school, eastern part of United States preferred. Salary $1800. B-56

SUPERINTENDENT or ASSISTANT MANAGER. Twenty years' experience on large variety of machine works. At present superintendent in a large plant. Desires position with machinery manufacturing concern. New England preferred. B-57

SALES ENGINEER. Mechanical engineer opening sales office in Detroit in near future wishes to handle complete line of power-plant machinery and specialties on salary or commission basis. Must have liberal commissions. Will push a good line and secure results. References. B-58

ENGINEER desires position as assistant manager or superintendent. Will consider position as chief engineer or resident engineer. Location immaterial. B-59

MECHANICAL ENGINEER who has done considerable consulting, general plant layout and supervision desires to make new connections with responsible concern or established office. B-60

ASSISTANT to PRODUCTION or EFFICIENCY EXECUTIVE. Technical graduate, age 27. Five years' experience in machine shop, drafting, and designing. Familiar with modern production methods and possesses originality, integrity, and accuracy. Desires permanent position with progressive company. Location immaterial. B-61

PROFESSOR OF MECHANICAL ENGINEERING, technical graduate, age 40, M.E., with 17 years' experience in teaching, engineering and consulting work. Practical experience in commercial engineering; specialized in steam power plants. For a number of years head of department of mechanical engineering in leading university. At present head of departments of mechanical and electrical engineering in university of good standing. Location abroad, China preferred. B-62

CHIEF ENGINEER, EXECUTIVE or MASTER MECHANIC. American, age 38. Held positions of chief engineer for two large chemical works. Fifteen years' experience handling men and production in large plants. Thorough shop and foundry man; also power-house engineer, competent to assume full charge of all mechanical work in a large plant. Desires position with a large industrial plant or other responsible position. Highest references; can prove ability. B-63

SUPERINTENDENT. Member, graduate in mechanical engineering. Thoroughly familiar with current practice affecting superintendency of medium-sized plant. Would consider change from present position, providing a small investment in the business would be considered. Location desired, Chicago. B-64

MECHANICAL ENGINEER or ASSISTANT MANAGER. Associate member, age 38. Twenty years' experience as shop foreman, chief draftsman, master mechanic and engineer. Has designed, constructed and operated machine shops, car shops, power and sub-stations, pumping plants, air-compressing plants, fire-protection systems, etc. Several years' experience designing and building conveyors, electric locomotives, cars, trucks, hoisting machinery, foundations, structural-steel work, and buildings. Competent to assume responsibility and produce results. Plant now erecting about completed. Available in thirty days. Salary $3000 per annum. B-65

EFFICIENCY ENGINEER. Technical graduate, age 32. Eleven years' experience, covering construction and operation of power plants and central stations. Specialty, boiler economy; can furnish excellent references on this point. Now seeks engagement with firm desiring results that a capable engineer—not a magician—can produce. Minimum salary $250 per month in United States and $300 and expenses elsewhere. B-66

SUPERINTENDENT or ASSISTANT GENERAL MANAGER. Mechanical engineering graduate, age 27. Technical apprenticeship with motor-truck company. Successful experience in designing, handling men, increasing production, reducing costs and installing modern methods. Some purchasing and selling experience. Now employed as superintendent by well-known concern manufacturing large and small interchangeable-part machines. Desires better opportunity for future. B-67

MECHANICAL ENGINEER. Graduate University of Illinois, age 35, married. Five years' practical experience in shops, engineering and sales offices. Five years' outside erection, inspection, trouble work, and testing of power-plant equipment and accessories, including boilers, Corliss, oil and gas pumping engines, steam turbines, condensers, electrical equipment. Thorough, capable and aggressive, possessing executive ability and eager for responsibility where results are desired. Prefers position with consulting engineers or firm requiring traveling constructor, inspector, tester or sales engineer. Best of references from past and present employers as to integrity, honesty and ability. B-68

SUPERINTENDENT, MASTER MECHANIC or EQUIPMENT ENGINEER. Age 33. Fourteen years' experience in drawing and stamping of sheet metal. At present assistant equipment engineer in plant having 10,000 employees. B-69

COMBUSTION ENGINEER. Technical graduate about to end four-year term as head of smoke-inspection department of large city, desires to connect with some concern to whom his experience would be of value. Prominent in national smoke-abatement movement. B-70

PUBLICITY ENGINEER. Mechanical graduate, age 33, married, excellent health. Thoroughly experienced in the advertising of mechanical equipment. Expert in the preparation of sales literature, trade paper advertising, and sales correspondence. Minimum salary $200 per month. Available for interview any time in New York City or vicinity. B-71

MECHANICAL ENGINEER. Associate-Member, age 30, technical training. Three years on civil engineering work: foundation, concrete, steel, building and power-house erection. Four years' mechanical engineering experience, on boilers, engines, special apparatus, hydraulic machinery, shop work, producer-gas engines and generators, industrial plant work. Two years in electrical work, on a.c. and d.c. generation, transmission and distribution. Good executive, desires to specialize. B-72

EXECUTIVE ENGINEER, ASSISTANT TO EXECUTIVE OFFICER or CONSULTING ENGINEER. Graduate of leading technical school. Twelve years' experience as special engineer in shop, factory, sales and general office administration work. Good organizer and experienced in directing men. B-73

JUNIOR MEMBER. Stevens graduate, with varied experience in the development of machinery and scientific inventions, wishes to connect with aeroplane or automobile manufacturer. At present engineer for a large electrical manufacturing company. Available on reasonable notice. B-74.

ENGINEERING SURVEY

A Review of Engineering Publications in All Languages. All the leading periodicals of the engineering world, embracing over 1000 different publications, are received at the Library. These are systematically examined for review each month in the Survey.

SUBJECTS OF ABSTRACTS

ARRANGED IN THE ORDER OF THEIR APPEARANCE IN THE SURVEY.

Particular attention in this issue is called to the section Internal-Combustion Engineering, especially the abstracts of articles on the development of the use of Diesel engines in shipping, both in America and in Europe. It is unfortunate in this connection that the data of the article in *Motorship* describing the motive power of the M. S. *Deutschland* are so obscure. With all this, however, the article represents a good example of enterprising work in the field of engineering journalism and contains data which are not otherwise available.

THIS MONTH'S ARTICLES

In a paper before the Annual Meeting of the Society of Automobile Engineers, now transformed into Society of Automotive Engineers, Capt. V. E. Clark and his associates in the Signal Corps present a brief discussion of some problems in aeroplane construction. This paper is in line with the policy inaugurated by Col. George O. Squier (compare his paper presented in the Engineering Survey for January, 1917) of inviting the collaboration of the engineering profession at large in the working out of technical problems by the Aviation Branch of the War Department.

In the section Engineering Materials attention is called to an advance notice of a technological paper of the Bureau of Standards on the manufacture and properties of sand-lime brick.

In the same section will be found an abstract of a paper on Heat Treatment of High-Speed-Steel Tools, the authors of which show how important it is to carefully control the hardening temperature and to apply to each particular steel the proper heat treatment.

The Resistance of Lubricating Oils to Emulsification is discussed in another advance abstract of a technological paper of the Bureau of Standards, where it is stated that the majority of the oils on the market are either very good or very poor. A stirring test is suggested as being more sensitive than chemical tests only.

Sawdust Firing on a large scale as practiced at the Singer plant at South Bend, Indiana, is described in an abstract from an article in *Power*.

From the *American Gas Engineering Journal* are abstracted data of interesting experiments on the measurement of flow of unpurified gases at high temperature by means of pitot tubes, which show that the flow of hot gas can be measured in this way and that the temperature of the gas does not apparently affect the tube or interfere with the indications of the gage, at least when the measurement is carried on for a limited period of time.

In the section Hydraulics are described experiments on the effect of sudden enlargement upon the flow of water in pipes, likewise conducted by means of pitot tubes. In this case a special attachment described in the abstract was used for facilitating the set of the tube. A modified Borda formula is suggested for expressing the loss of head in feet due to sudden enlargement.

In the same section is presented an abstract of a paper on the Determination of Capacity and Design of Wood-Stave Pipe.

A novel two-cycle two-cylinder oil engine developed in this country is described: it is characterized by the employment of a cylinder in which operate two working pistons opposite to each other. A special arrangement for uncovering the exhaust ports is used.

Several abstracts are presented on Diesel engines. From a Bulletin of the Iowa State College are abstracted data obtained from a study of oil engines in Iowa power plants.

Another abstract describes in detail the matter of piston and small-end lubrication in Diesel engines. This discussion covers the subjects of selection of lubricating oil and design of lubricating system.

A paper read at the Annual Meeting of the S.A.E. by Prof. Walter T. Fishleigh and W. E. Lay presents data of a very interesting investigation of the heat-balance performances of automobile engines, including a complete heat balance for certain runs.

Locomotive-axle failures due to improper manufacture are discussed in an abstract from the report of an engineer of the Interstate Commerce Commission.

The erosive effect of steam on turbine-blading material formed the subject of an investigation carried out in the

post graduate department of the Naval Academy. While the investigation was only of a preliminary nature, the data obtained are already of considerable interest.

Another article in the same section, Steam Engineering, describes the use of Curtis steam turbines and Alquist reduction gears in the propulsion of cargo ships. From an article abstracted from the *General Electric Review* it appears that the abnormal conditions of American freight shipbuilding are now all favorable to the development of standardized production and to the use of the class of machinery here described. Data are presented on the comparative economy of reciprocating engine- and turbine-propelled cargo ships, showing considerable economy in favor of the latter class.

The Moore steam turbine, a newcomer in this line of production, is described from an article in *Power*.

From an article in *Engineering* is abstracted a discussion of the Willans Line for Steam Turbines, where it is shown how to obtain a corrected Willans line, and what a corrected line represents.

Aeronautics

Some Problems in Aeroplane Construction, Capt. V. E. Clark, Capt. T. F. Dodd, and O. E. Strahlmann

Enumeration with brief remarks of some important problems connected with the construction of aeroplanes intended for military use in the United States, some of these problems also applying, however, to aeroplanes built for commercial and sporting purposes.

The paper gives definitions of the main classes of military aeroplanes, viz., strategical-reconnaissance machines, tactical-reconnaissance machines, field-artillery fire-control, long-range bombers, pursuit machines and over-sea reconnaissance machines.

As to problems in construction, the question of two propellers is discussed in some detail. Methods of reducing the vibration are touched on somewhat cursorily. Gasoline-supply systems, on the contrary, are discussed in considerable detail and illustrated by drawings.

Of the other subjects, the following are touched on more or less: Metal construction for aeroplanes; flexible piping; muffler requirements; shock absorbers for landing gear; brakes required when landing; floating landing gear; gasoline-supply gage; fire safety devices; altitude adjustment for carburetor; firing machine gun by engine shaft through the disk of the propeller; variable radiators; ignition and cooling systems.

The paper discusses in particular detail the two important problems of variable-camber wing and propellers with variable pitch angle.

The question of propeller stresses is also discussed in detail and illustrated by several curves indicating the various stresses at various points of the propeller. (*S. A. E. Bulletin*, vol. 11, no. 3, December 1916, pp. 213-236, 15 figs., *g*)

Engineering Materials

The Manufacture and Properties of Sand-Lime Brick, Warren E. Emley

Sand-lime bricks are made of sand and lime, hardened by exposure to the action of steam at high pressure. They compete in numerous localities with common building bricks made of clay. There is a widespread demand for information as to just what sand-lime bricks are, how they are made, and what properties one may expect them to have. In this paper an attempt has been made to compile this information and make it accessible. A short theoretical discussion leads to certain conclusions as to the desired properties of the raw materials —sand and lime. The different steps of the process of manufacture are then taken up in detail, and comparisons made of the different mixing, pressing, and hardening operations as carried on in various factories. The testing methods generally employed for the examination of common building bricks are described in detail, and a summary is given of the results obtained when sand-lime bricks are subjected to these tests. An appendix contains detailed descriptions of the equipment of seven typical factories. (Abstract of *Technologic Paper* no. 85, Bureau of Standards)

Identification of Light-Gray Inclusions, George F. Comstock

There seems to be a common opinion among metallographists that all light-gray inclusions seen with the microscope in polished sections of steel are manganese sulphide. Slate-colored inclusions are considered to be silicates, and dove-gray inclusions manganese sulphide. This, however, is not correct, and scale which is apt to accumulate along the edge of any piece of steel if it be well polished and preferably unetched, will show light-gray in appearance. As a matter of fact, however, it is not manganese sulphide at all but chiefly iron oxide, and contains sulphur only as an impurity.

It therefore becomes important to find a method of distinguishing oxides from sulphides. It has been found that this can be done by the use as etching material of boiling alkaline sodium picrate, which produces blackening of the sulphides. This action seems to be due to an actual solution of the manganese sulphide by the etching liquid, so that instead of a smooth, polished surface we now have a surface full of pits or hollows where the sulphides were, and as these hollows do not reflect any light back into the microscope with vertical illumination, they appear black in the field of vision.

At the same time this liquid does not attack oxide inclusions at all. A further advantage of the use of this solution for the described purpose is that it is already used for etching cementite in high-carbon steel and is, therefore, familiar to metallographists.

The article contains numerous microphotographs showing the application of the described method, (*The Iron Trade Review*, vol. 59, no. 24, December 14, 1916, pp. 1195-1197, 17 figs., *eA*)

Notes on the Heat Treatment of High-Speed-Steel Tools, A. E. Bellis and T. W. Hardy

The problem of heat treatment of high-speed steel becomes increasingly important as the design of cutters becomes more and more complicated with the growth of efficiency of mechanical operations. While hundreds of dollars are spent in the design and manufacture of milling cutters of special form for rapid production of duplicate or interchangeable parts, the final efficiency of the operation depends on the ability of the tool to perform the work, and this in its turn depends on the heat treatment given it. In order to be on the safe side, the average tool hardener uses a temperature much too low to give the best results with the high-speed steel he uses. In the case of cutters which are finished to a given diameter before hardening, it is impossible to grind the tool after hardening, so that it is essential that the surface be

protected from oxidizing or decarbonizing. In this paper are described some experiments on hardening high-speed steel in which metallographic means were used to determine the correct hardening temperature.

Six specimens from the same bar of each kind of steel (5 kinds were taken) were hardened from different temperatures and photomicrographs made. The temperature from which the piece was hardened is given under the photomicrograph in each case (cp. Fig. 1). Photographs were made of the longitudinal section, care being taken to grind off the outer surface. The specimens ¼ in. square in section were first preheated at 1500 deg. fahr. and then quickly placed in the high-speed furnace already heated to the desired temperature, left at this temperature for one minute, and quenched in oil.

In interpreting the micrographs the author regards that at

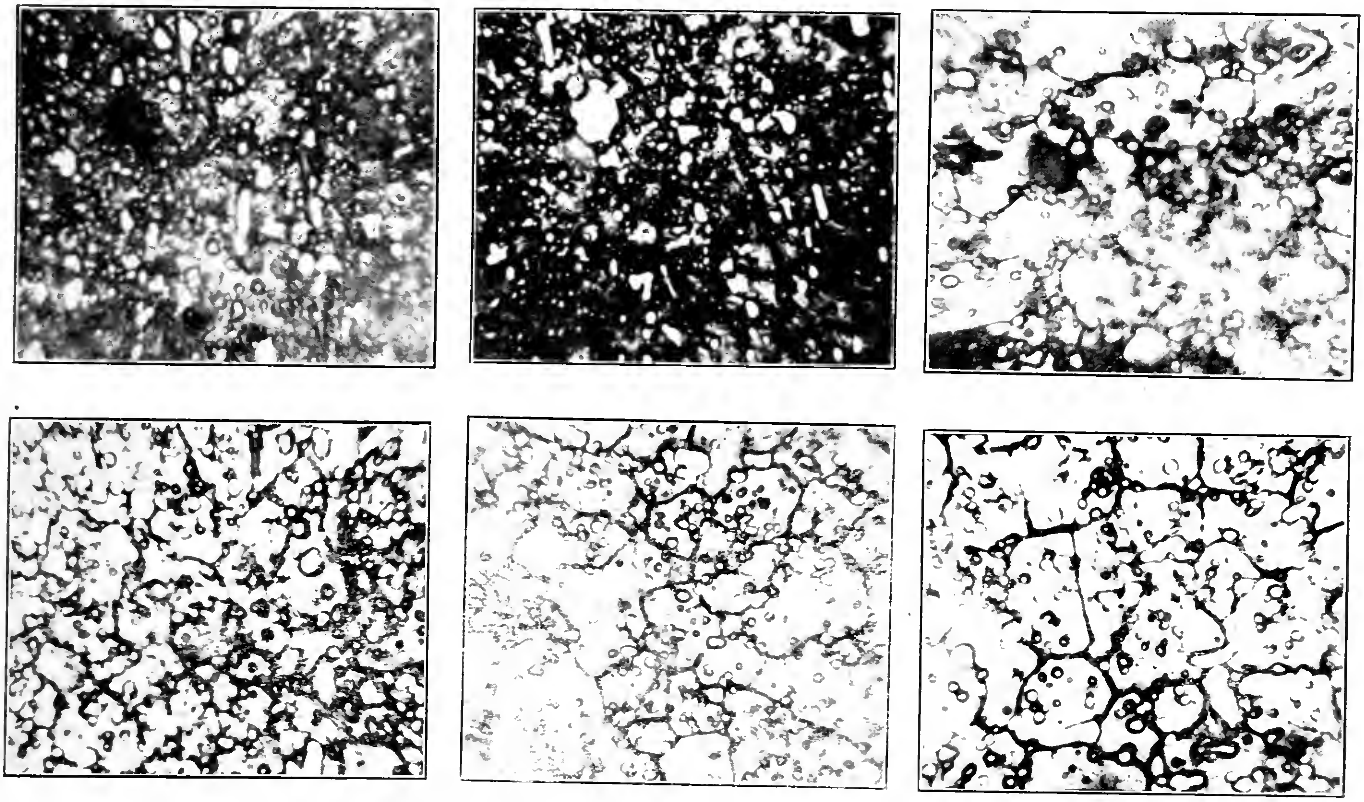

Fig. 1 Microphotographs of Specimens of High-Speed Tool Steel Treated at Various Temperatures
Upper Row (from left to right): 2050, 2100, 2200 deg. fahr. Lower Row (left to right): 2250, 2300, 2350 deg. fahr.

2100 deg. fahr. as a dark matrix showing a large excess of free carbide; as the temperature is raised, more and more of the carbide dissolves and the network structure of austenite is more noticeable.

In general, the steels that show some excess carbide even at the maximum hardening heat are the most efficient. These as a rule are the steels with high tungsten content; they harden from a higher temperature and over a wider range than the lower-tungsten steels, and for this reason do not require as careful treatment as the latter. On the other hand, the steels with lower tungsten and higher vanadium give better results when hardened at the lower-tungsten temperatures than do higher-tungsten steels when these are hardened at the same low temperatures. The comparison is not so advantageous to the lower-tungsten steels when the steel with higher tungsten is given the proper hardening heat.

It is highly important to carefully control the hardening temperature and to apply for each particular steel the proper temperature. The custom of using only one "high-speed temperature" for all steels is very poor practice.

A good deal of trouble is experienced in hardening through oxidation at high temperatures. The use of a barium chloride bath to eliminate this difficulty has the disadvantage that the surface of the tool becomes decarbonized. A method that has proved satisfactory is to place the tools, after preheating, in the reducing temperature of a carbon-resistance electric furnace already heated to the required temperature. The very short time necessary to get the tool to the temperature of the furnace eliminates injurious surface effects.

The increased efficiency and cutting power of tools that have received the proper heat treatment are out of all proportion to the time given to the study of the particular steel involved and to the care given the work. (*Bulletin of American Institute of Mining Engineers*, no. 121, January 1917, pp. 61-68, 5 plates. *epA*)

Report of Committee on Specifications for the Purchase and Preservation of Treatable Timber

Only parts of this report are here abstracted.

As regards the selection of preservatives, the report states that from the standpoint of permanent protection of wood against decay and marine borers, coal-tar creosote is the best available preservative for general purposes. It possesses the necessary theoretical requirements and has stood all practical tests through many years' use under varying conditions of service and in many different kinds of materials.

Zinc chloride is of great importance as a preservative and deserves full consideration in regions of low precipitation, in dry sections, and where general low cost is essential. While

the life of zinc-treated material is usually less than that of creosoted, the expense is also less.

Factors to be considered in comparing preservatives:

1 The toxicity of the preservative, namely, its ability to prevent decay.
2 The ability of the preservative to penetrate the wood.
3 The permanency of the preservative in the wood.
4 The effect of the preservative on the strength of the wood.
5 The effect of the preservative on the corrosion of spikes and plates, and the operation of block signals.
6 The cost of the preservative.
7 The uniformity in composition of the preservative and the ease of securing it.
8 The combustibility of the preservative.
9 The ease of handling the preservative and wood treated with it.
10 The ease with which the penetration of the preservative can be determined.

In treating with creosote it is recommended that a maximum injection of creosote sufficient to insure the penetration of all treatable wood be required. All the sapwood and as much of the heartwood as is possible for the particular species shall be thoroughly impregnated. This applies equally to full-cell and empty-cell treatments.

In treating with zinc chloride it is essential that all timber be treated to refusal.

As to selection of treatable timber, the fundamental requirements of structural timbers for treatment are strength and capacity for treatment to an extent which will insure protection against decay on all exposed surfaces. A penetration of one-half inch on the heart faces may be recommended as a safe minimum on structures above ground.

The report covers also the subjects of restrictions on knots, shakes, checks, cross-grain, sapwood, etc.; track ties; piles; preparation of timber for treatment, and treatment proper. (Abstracted from advance copy of report to be made at the Annual Meeting of the American Wood Preservers' Association in New York. January 23-25. 1917.)

THE RESISTANCE OF AN OIL TO EMULSIFICATION, Winslow H. Herschel

In forced-feed lubrication, such as is used with high-speed engines and turbines, there is often trouble due to the emulsification of the oil. Service tests are not practicable, on account of the time and trouble involved, so that there is great need of a laboratory test. Moreover, it is highly desirable that the test should make it possible to express the resistance of an oil to emulsification by a single numerical value, as experience has proved that it is almost impossible to enforce in a contract any less definite specification.

A study of the literature showed that though several emulsification tests were described, they were all more or less indefinite, and no one of them was in general use. It was therefore necessary to devise an entirely new test, which may be briefly described as follows:

Twenty cubic centimeters of the oil to be tested, and double that volume of distilled water, are heated to 55 deg. cent. (130 deg. fahr.) in a 100-cc. cylinder of 26 mm. (1 in.) inside diameter, and stirred for five minutes at a speed of 1500 r.p.m. The paddle is simply a plate of metal, 89 x 20 x 1.5 mm. ($3\frac{1}{2}$ x 13/16 x 1/16 in.), approximately. Since the test is not sensitive to slight changes of paddle dimensions, they need not be exact, and no calibration is required. The cylinder and contents are allowed to stand at the same temperature, and readings are taken at more or less frequent intervals (according to the type of oil) of the volume of oil settled out from the water. From these readings a maximum rate of settling, called the "demulsibility," is easily taken from a table.

A German test, used for steam-engine cylinder oils, would appear at first sight to discriminate against the good oils containing compounding in the attempt to eliminate the poor oils which contain soap. Examination of the experience with the test, however, shows that the method of agitation is not very effective, so that only oils which contain soap will emulsify. Good oils, even if they are compounded, will not emulsify. The test here described might be so modified as to make it applicable to steam-engine cylinder oils, but this has not yet been attempted, and in considering the results obtained with the test for demulsibility, compounded oils have been omitted, except where noted.

It has been found that the majority of oils on the market are either very good or very poor. The best transformer, dynamo and turbine oils settle out in a minute or less, thus showing a demulsibility of 1200 cc. per hour, which is the highest value on the arbitrary scale adopted. On the other hand, when an emulsifying marine-engine or crank-case oil is tested, no oil will settle out of the emulsion up to the end of the hour that the test is continued, and the demulsibility is recorded as zero.

Comparison with chemical tests shows that the stirring tests are the more sensitive, and this is in agreement with the experience of others. This explains why it has been such a troublesome problem to chemists, why one oil would emulsify and the other would not, when according to their tests, both oils were equally pure. The stirring test shows that a minute amount of impurity, which cannot be detected by chemical means, will cause a marked increase in emulsification.

Oils which have a suitable demulsibility will not emulsify in use, but there is still the trouble that, after a considerable length of time, they may disintegrate and deposit sediment, due to oxidation, polymerization, or some other similar chemical change. On this account an investigation of used oils was undertaken, and it was found that there was a marked decrease in demulsibility with continued use. The conditions of operation are so different in different power plants that exact values can not be given for the rate of deterioration to be expected, but it is believed that the test should prove of great assistance to power-house engineers in keeping track of the deterioration of the oil in their plants. (Abstract of *Technologic Paper* no. 88, Bureau of Standards)

Fuels and Firing

NEW METHOD OF INDICATING DENSITY OF SMOKE, as Installed on the U. S. S. *Conyngham,* Rear-Admiral R. T. Hall, U. S. N.

The system installed on the after stack of the ship consists of a light transmitter installed on one side of the stack, a light receiver installed on the opposite side, and an indicating meter with suitable control appliances installed in the boiler room.

The basic principle of operation of the system is dependent on the peculiar property of selenium, namely, that its electric resistance is inversely dependent on its illumination.

In this case a beam of light is projected across the stack, and its intensity when it reaches the selenium varies with the density of the smoke. Hence, if a plate of selenium of suitable structure is placed opposite to the source of projected light, its electrical resistance will vary with the density of the smoke, and by connecting the selenium plates in series with a suitable indicating meter to the source of electric-current supply, variations of smoke density will be made manifest by variations in the current flowing through the meter.

On a metal plate in the boiler room are installed the smoke-indicating meter and a potentiometer, the latter being provided with a slidable brush for adjusting the potential on the selenium plate and serving as a simple and effective means for setting the indicator on the "clear" indication, as when no smoke is issuing from the stack. The system is connected with the ship's lighting main at 125 volts. (Paper before the Annual Meeting of the Society of Naval Architects and Marine Engineers, November, 1916, from an abstract in the *International Marine Engineering*, vol. 21, no. 12, December 1916, p. 539. *d*)

Sawdust Firing at the Singer Plant at South Bend, Thomas Wilson

One of the large branch factories of the Singer Manufacturing Co. is located at South Bend, Ind. Here all cabinet work and stand-part operations are performed, from the raw material to the finished product. A large plant was required to supply these works with steam for heating, factory use and power purposes. There are three boiler plants with a total of 3016 boiler horsepower in 18 units, consisting mostly of small water-tube boilers provided with plain grates and arranged for burning coal and sawdust.

The most interesting feature of the plant is the system for burning the sawdust.

The sawdust is fed to the boiler furnaces independently of the coarser material. The collector system (Fig. 2) consists of four steel towers outside the machinery building. All the various trunk ducts are carried into these main towers, the suction being furnished by eight large motor-driven fans, two for each tower (the fans are driven by four 180-h.p. synchronous motors). Four small fan equipments in series, each somewhat larger than its predecessor, remove the sawdust which drops into the collectors and deliver it successfully from tower to tower until it is finally discharged into the collector located above the boiler room.

Upon leaving this latter collector the sawdust drops through chutes into a horizontal scraper or flight conveyor. Through gates in the conveyor bottom the sawdust drops into six steel tanks, one for each boiler. As soon as the first tank is filled, the gate may be closed or in any event the sawdust will automatically pass on and drop into the next opening. These tanks are on a level with the firing floor. They are oval at the top and flare out at the bottom so that there will be no difficulty from the sawdust arching and lodging in the upper part.

At the bottom of each tank are two friction-disk-driven screw conveyors which carry the sawdust over and drop it into the chutes on top of the boiler furnaces. Means are provided for individual adjustment of the rate of feed of each furnace.

The method here described obviates the danger of unevenness of the fuel supply and excess of either air or fuel and permits of accurately controlling both fuel and air.

Since the power plant has been installed, general conditions forced certain changes. It had been the plan to store the excess of sawdust in the summer months when the demand for fuel is low, and use the surplus to supplement the supply during the heating season. Various conditions have greatly reduced the output of waste available for use as fuel, and coal has to be used at times. When so used it is burned exclusively at night for supplying steam for the dry-kilns, pumps and lighting.

The original article reports data of tests of the boilers with sawdust fuel. It is of interest to note that with this fuel a superheat of 560 deg. fahr. is attained, an evaporation of 4.33 lb. of water per pound of fuel as fired, and an equivalent evaporation per pound of fuel from and at 212 deg. fahr. of 5.09 lb. of water. The efficiency of boiler and furnace combined, based on dry fuel, was found to be 64.9 per cent. (*Power*, vol. 44, no. 25, December 19, 1916, pp. 838-844, *d*)

A unique scheme is used in the design of the apparatus for controlling the high-duty elevator pumping engines at this plant, described in *Power*, vol. 44, no. 26, December 26, 1916, p. 874.

Hydraulics

A Theory of Fluid Friction, William Gatewood

An attempt to correlate the laws of fluid motion having a bearing on the subject of frictional resistance, and to formulate a theory.

This theory may be summarized as follows:

1 Frictional resistance per unit of surface varies as the square of the equivalent rubbing velocity determined by considering the flow to be laminar.

2 Friction between adjacent laminæ of the fluid varies as the rate of change of velocity occurring at their boundary.

3 In the case of a fixed body and a moving fluid, the frictional resistance experienced up to a given distance abaft the cutwater must be balanced by the loss of head in the wake at the same distance abaft the cutwater.

4 The width of the wake at a given distance abaft the cutwater and the reduction of velocity in the wake at various distances from the fixed body may be determined by the consideration that the loss of head outboard of any lamina is equal to the frictional resistance experienced by the lamina before reaching the given distance from the cutwater.

5 The determination of the loss of head in the wake is complicated by the condition that the volume of the fluid passing the fixed body is not altered, although the velocity in the wake is decreased. The consequent elevation of the surface of the fluid becomes of considerable importance when the velocity is relatively small or the reduction in velocity occurs quickly on account of roughness of surface.

6 The energy and action of the eddies may be assumed to be such that the loss of head may be determined as though the flow was entirely laminar. (Paper read before the Annual Meeting of the Society of Naval Architects and Marine Engineers, November 1916, abstracted from *International Marine Engineering*, vol. 21, no. 12, December 1916, pp. 543-544. *t*)

The Effect of Sudden Enlargement upon the Flow of Water in Pipes, T. J. Rodhouse

Paper describing experiments conducted for the purpose of determining the effect of sudden enlargement of section upon the flow of water in pipes. Coincidentally the action of the pitot tube has been studied under disturbed conditions of flow,

with a view to determining the conditions under which the tube may be relied upon to give accurate indications.

The paper describes the apparatus used. The investigations were limited to the two cases of the effect of sudden enlargement from pipes of 1 in. and $1\frac{1}{2}$ in. in diameter to one whose diameter is 2.096 in. The pipes were straight, smooth, seamless drawn brass tubing.

The pitot tube consisted of a straight cylindrical german silver tube $\frac{1}{16}$ in. in diameter and projecting about $\frac{3}{32}$ in. from the end of a larger brass tube of $\frac{5}{16}$ in. external diameter by $\frac{3}{16}$ in. internal diameter having hose connections and a setting arm or pointer for indicating correctly the position of the impact opening when placed in the pipe. The tube had only a single impact opening $\frac{1}{32}$ in. in diameter located passes through a thumbnut set in the upper end of the frame. By turning the thumbnut the tube can be quickly and accurately set and firmly held at any desired position in the traverse. The author attributes the uniformity of readings in practically all of these traverses largely to this accurate means of controlling the position of the impact point. The impact opening was circular, $\frac{1}{32}$ in. in diameter, and in making a traverse the opening was kept pointing directly upstream, its axis always parallel to the axis of the pipe.

The writer suggests the following expression for the loss of head in feet due to sudden enlargement:

$$H_b = K\left(\frac{A_2}{A_1} - 1\right)^2 \frac{V_2^2}{2g}$$

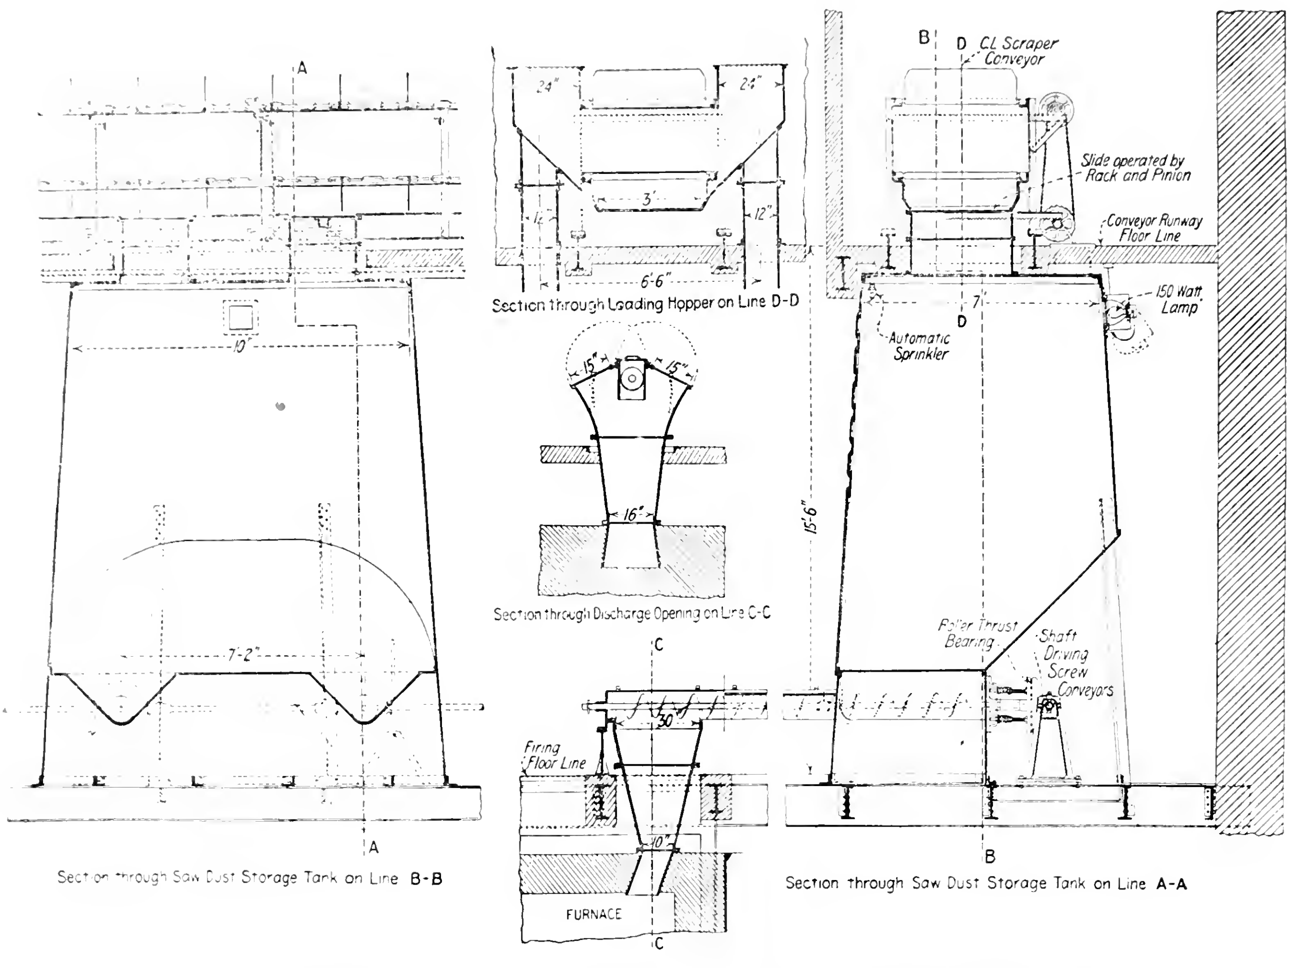

FIG. 2 SAWDUST-FIRING PLANT OF THE SINGER MANUFACTURING CO., SOUTH BEND, IND.

0.04 in. from the end, with its axis intersecting at right angles the axis of the tube. The static pressure was taken at the piezometer at the wall of the pipe in the same plane with the tube. The pressures from the impact opening and the static piezometer were conducted to the triple differential gage through $\frac{1}{4}$-in. heavy cotton-insertion rubber tubing.

An attachment invented by Prof. G. S. Williams for facilitating the setting of the tube was used. It consists of a brass frame whose base fits snugly over the stuffing box and is securely clamped there by three set screws. The frame is slotted on each side for guiding the central tube which receives the main stem of the pitot tube, holding it in place by a large thumbscrew. This central tube is threaded its full length and which is a constant, times the theoretical loss by Borda's formula. In this equation, A_2 and A_1 are the areas of the larger and smaller pipes. V_2 is the mean velocity in feet per second in the larger pipe (in the formula on p. 59, apparently by typographical error, V is used.—Ed.) and $g = 32.2$; K is a coefficient. Two tables are given in the article in which values of K are given. These tables show a slightly smaller loss of head as observed than the computed theoretical loss due to enlargement as expressed by Borda's formula. In the opinion of the writer, this discrepancy may be due to one or two causes, or perhaps to both. Either the frictional loss which enters into this equation is less than that which occurs in the case of the straight pipe with undisturbed flow, due perhaps to the cen-

ter of velocity of the jet as it enters the larger pipe and continues in this condition for some distance before spreading out and obtaining its full pressure and frictional effect on the wall of the pipe, or else the loss in the impact of the particles in the expanding jet due to the enlargement of the pipe section does not follow exactly the law for sudden enlargement as expressed in Borda's formula, failing to obey this law, perhaps, on account of conditions which might be considered as producing a water cone of gradual instead of sudden enlargement. The author prefers the latter theory as a possible explanation rather than the former, for it is difficult to imagine any reduction in frictional resistance less than that for straight pipe in the region of these greatly disturbed conditions.

As regards the pitot tube, the final results obtained in this investigation are summarized by the author in the following words:

1 The pitot tube measures with a fair degree of accuracy, always within two or three per cent and more frequently within one per cent, the velocities of flow in a pipe where the resultant motion of the water throughout the entire cross-section at the point where the tube is inserted is a forward motion, and where the distribution of velocities is symmetrical about the axis of the pipe.

2 The pitot tube is a means by which eddies or whirls caused by obstructions in the pipe may be detected, but it will not measure with any degree of accuracy the discharge of a pipe when inserted in the immediate region of such eddies.

3 The rating coefficient of discharge of the pitot tube for normal conditions cannot be applied in the case of abnormal conditions produced by sudden enlargement where eddies exist, but immediately below the region of eddies the rating coefficient of discharge may be applied with a fair degree of accuracy.

4 The eddies produced by sudden enlargement of section extend for the short distance of only about two or three diameters below the enlargement.

5 The disturbance caused by sudden enlargement of section produces abnormal conditions in the distribution of velocities which continue down the pipe for a distance of about 35 diameters.

6 The ratio of the mean velocity to the velocity at the center, $\frac{V_m}{V_c}$, increases in value, in the case of sudden enlargement, from a minimum near the point of enlargement to a maximum at a point about 11 diameters downstream, after which it begins to gradually decrease, approaching the value of the ratio for flow in straight pipe at a distance of 35 diameters below enlargement.

7 The pitot tube reversed, i. e., the impact point turned downstream, gives a negative pressure head, which reduced to velocity, negative, gives a value whose ratio with the velocity in the upstream direction is fairly constant for any given form of tube. But the relative values of the downstream readings to the upstream readings for different forms of tubes vary greatly. The maximum negative pressure or suction action at the impact point of the pitot tube occurs when the direction of the axis of the opening is approximately perpendicular to the direction of flow. (*The Cornell Civil Engineer*, vol. 25, no. 2, November 1916, pp. 49-61, 2 figs. *et*)

The Flow of Water in Wood-Stave Pipe, Fred C. Scobey

A paper on the determination of capacity and on the design of wood-stave pipe, based both on the theoretical investigations and field tests.

The author offers a new set of formulæ based on experiments on round wood-stave pipe described in engineering literature and supplemented by an extensive set of experiments in which he was aided by Ernest C. Fortier. These formulæ are as follows:

$$H = \frac{7.68\,V^{1.8}}{d^{1.17}} = \frac{0.419\,V^{1.8}}{D^{1.17}} \ldots\ldots\ldots\ldots [1]$$

$$V = 1.62\,D^{0.65}\,H^{0.555} \ldots\ldots\ldots\ldots [2]$$

$$Q = 1.272\,D^{2.65}\,H^{0.556} \ldots\ldots\ldots\ldots [3]$$

where H is the head of elevation lost in overcoming internal resistances within a fairly straight pipe of uniform size per 1000 linear feet of pipe; V the mean velocity of the water during test in feet per second; D the mean inside diameter of the pipe in feet; d the mean inside diameter of the pipe in inches; and Q the mean discharge of the pipe during the test in second-feet.

The exponents of V and H in these formulæ are the same as those in the corresponding formula proposed by E. A. Moritz (*Engineering Record*, vol. 68, no. 24, p. 667). The difference in the formula is caused by the divergence in the intercept curves in the logarithmic diameter shown in the original article. As indicated in these curves, the difference becomes greater as the larger pipes are approached, for the reason that all data for large pipes in the Moritz formula came from his tests on the 55¾-in. Mabton pressure pipe.

The writer comes to the following conclusions:

1 That the new formula herein offered is the best now available for use in the design of wood-stave pipes, as its application meets (within one per cent) the mean of all observations and the mean capacity of all wood pipes upon which experiments have been made.

2 That a very conservative factor of safety should be used where a guaranteed capacity is to be attained.

3 That the Kutter modification of the Chézy formula is not well adapted to the design of wood-stave pipes.

4 That the data now existing do not show that the capacity of wood-stave pipe either increases or decreases with age. This statement of course does not consider sedimentation, a purely mechanical process.

5 That if silted waters are to be conveyed, the pipe should be designed for a working velocity of from five to ten feet per second.

6 That if sand is present in the water, the design should be for a velocity of about five feet per second, which will be high enough to carry out a large part of the sand and at the same time not so high as to seriously erode the pipe. The better method, of course, is to remove the sand by sumps or other means.

7 That air should be removed from the intake end of every pipe line, especially when the capacity load is approached.

8 That wood pipe will convey about 15 per cent more water than a ten-year-old cast-iron pipe or a new riveted pipe, and about 25 per cent more than a cast-iron pipe 20 years old or a riveted pipe ten years old. (*United States Department of Agriculture, Bulletin No. 376*, 96 pp., 7 figs. and several large plates, *et.*1)

Internal-Combustion Engineering

An American Oil Engine, Frank C. Perkins

Description of a novel two-cycle two-cylinder oil engine developed at Milwaukee, Wis.

This oil engine works on the two-cycle Diesel principle,

and is characterized by the employment of a cylinder in which operate two working pistons opposite to each other, as shown in Fig. 3. Shortly before the upper working piston has reached its uppermost position, it uncovers the exhaust ports arranged along the whole circumference of the cylinder, at which time the burned gases from the previous working cycle pass through an exhaust manifold into the surrounding atmosphere.

Immediately after this the lower working piston uncovers its scavenging ports likewise arranged along the whole circumference of the cylinder, through which the scavenging air rushes in, driving out the remaining products of combustion and charging the cylinders with fresh cold air. The placing of the ports for the admission of scavenging air at the cool lower end of the cylinder allows cold air to be admitted and insures a more effective charge. During the following compression stroke of the two working pistons the charge is compressed to a temperature well above the ignition point of the fuel employed.

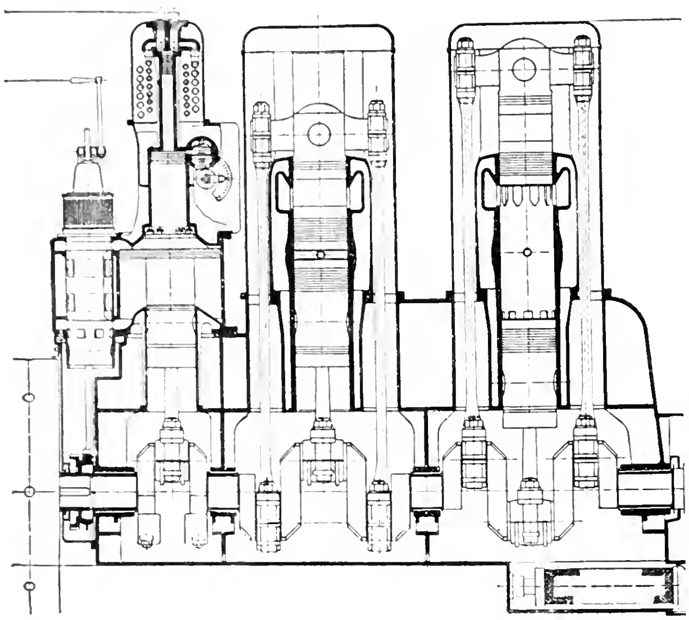

Fig. 3 Opposed Pistons, Two-Cycle, Two-Cylinder Oil Engine

The engine built produces 60 b.hp. when operating at the speed of 400 r.p.m. The cylinders have a bore of 6 in. and stroke of 14 in. It is stated that the forces developed by the combustion of the fuel are entirely taken up by the two working pistons with their connecting rods and cranks.

It is claimed that the air receiver is separated from the crank case, so that the dampness of the lubricating oil from the crank case cannot contaminate the scavenging air. The working output of the scavenging pump is small because it delivers the scavenging air to the receiver under a pressure of only 2 lb. per sq. in., which is entirely sufficient to clean the working cylinders of the burned gases. The compressed air for fuel injection is produced by a single-acting two-stage air compressor mounted in tandem over the scavenging pump, whose stepped piston is the extension of the piston from the scavenging pump. The air pressure in the injecting-air bottle delivered from the high-pressure stage should remain constant at about 1,000 lb. per sq. in. under the varying load of the engine. The compressor delivers a little more air than is required for fuel ignition, and this surplus, passing through a by-pass valve connected with the low-pressure stage of the compressor, is stored in the starting tank under a pressure of about 150 lb. per sq. in.

The valves on the compressor are of the automatic type. Special relief valves are fitted after every stage of the compressor to prevent excessive pressure in the air mains. The fuel pump is driven by means of helical gears direct from the crankshaft, and a separate plunger is provided for each working cylinder of the engine. The governor actuates the suction valve of the fuel pump in such a manner that the amount of fuel delivered to the working cylinders is in accordance with the load carried by the engine.

It is claimed that the combustion space between the two pistons, being a circular chamber without projections or recesses, constitutes the most efficient form of combustion chamber. The period of injection of the fuel into the working cylinder is variable in such a manner that the needle of the fuel-injecting valve remains open for a longer period when operating under a full load, and closes earlier when under a light load. This arrangement prevents the disturbance of combustion because the quantity of air needed for breaking up the fuel and injecting it into the combustion chamber is in accordance with the varying load of the engine. It reduces further the power output of the air compressor and gives the engine a high degree of speed variation.

The engine is started by means of compressed air at low pressure. By turning the starting lever the compressed air is admitted through a distributing valve to both sides of the piston of the scavenging pump, which now acts as an air motor and sets the engine in motion. It is stated that this engine can be started at a low air pressure of 150 lb. per sq. in., but the starting continues to be effective even should the pressure drop to 60 lb. per sq. in. The article also describes the forced-feed lubricator used on this engine. No data of tests are reported. (*The Isolated Plant,* vol. 8, no. 12, pp. 13-14, 2 figs., December 1916. *d*)

Diesel-Engine Construction in the United States

Up to a couple of years ago it cannot be said that there was any extensive production of Diesel engines in the United States, even though arrangements for it were being made. Since then, however, mainly because of the impetus given by the abnormal conditions in shipping, extensive developments have taken place. About a year ago three of the most important shipbuilding companies in the United States, having recognized that the large merchant motorship had come to stay, laid plans for the immediate and near future by securing constructional licenses from prominent European firms who had obtained practical success with high-powered marine Diesel-type oil engines.

Although Germany is the original home of the Diesel engine, they went for their designs not to that country but to Denmark and Holland, where greater strides have been made with the marine development. The William Cramp Ship and Engine Building Company secured a license from Burmeister & Wain, of Denmark; The New York Shipbuilding Company and the Newport News Shipbuilding & Dry Dock Co. licenses from the Werkspoor Company (Holland).

It is stated that no sooner had these firms concluded negotiations than they were overwhelmed with orders for steamships, which has somewhat delayed motorship building.

It is also stated that the shipbuilding yards controlled by interests connected with the Bethlehem Steel Company are now developing a Diesel-engine type under the supervision of engineers of that corporation.

In this connection, of considerable interest are data referring to a Diesel motorship designed by The New York Shipbuilding Company at Camden, N. J., to the order of an important American oil company.

She is a single-screw ship designed to carry oil in bulk, and is of the single-deck class with poop bridge and forecastle. Length overall, 260 ft.; breadth, 42.5 ft.; draft, 20 ft.; deadweight capacity, 3000 tons; indicated horsepower, 1360; speed loaded, 10 knots.

The engine is to be a six-cylinder, single-acting, four-cycle model of the Werkspoor pure-Diesel design. Cylinders, 22 in. bore by 39⅜ in. stroke; the total of 1360 i.hp. to be developed at 125 r.p.m.; mean effective pressure, about 100 lb. per sq. in.

The length of the engine overall will be 27 ft. 3 in., and height above shaft center, 16 ft. 9 in.; the net weight will be about 122 tons, while the total machinery weights are expected to be in the neighborhood of 220 tons. Auxiliaries will be steam-driven, and probably the exhaust gases from the main engine will partially be used for firing the donkey boiler, so as to economize on fuel.

An oil-fired or coal-burning steamer of the same dimensions and speed could not carry this amount of cargo and would, therefore, have a much lower earning power. In addition to this, the fuel bill of the motorship will be about one-fourth that of a steamer. Her tonnage bill will be less in proportion to cargo, and there will be no wages or food bill for stokers. Her oil-fuel bill for a 17-day voyage will be under $1000, this with oil at $1.50 per bbl.; but as she will take oil in Texas or Mexico, this cost will actually be reduced by 50 per cent. Hence it is expected that, as compared with a steamer of the same size, she will show high economic advantages. (*Motorship*, vol. 1, no. 8, December 1916, p 10, 1 fig. *dc*)

The Motive Power of the M. S. Deutschland, Russell Palmer

Description of the motive power of the merchant submarine *Deutschland* from data obtained from the officials of the company operating the vessel. The article is based upon a personal interview with Chief Engineer H. Kleis of the *Deutschland,* at New London, Conn., on November 6.

From data published in the article it appears that the engines are of the Krupp type and are built on the four-stroke cycle. Further, the well-known Krupp bronze construction is not used in this instance (it is stated that it has been retained only in the two-stroke-cycle motors which continue to be built), and steel and cast iron are employed instead.

According to the statement of the Chief Engineer, the submarine is fitted with two six-cylinder engines somewhat smaller than the regular Krupp submarine engine and somewhat simpler in construction.

As to dimensions, Mr. Kleis, in the first interview, stated that the cylinders have a bore of 45 cm. (17.35 in.) and a stroke of 60 cm. (23.4 in.). Subsequently, however, Mr. Kleis changed these dimensions to 40 cm. × 50 cm. He also stated that while these engines have a range of speed from 200 to 400 r.p.m., the ordinary operating speed is 380 r.p.m., i. e., not far from the maximum. Assuming that this maximum speed is correct, that would mean a piston speed of nearly 1600 ft. per min. and an output of almost 1300 b.hp., which, if true, is certainly remarkable. It seems, however, more likely that the ordinary operating speed is not 380, but 280 r.p.m. A stroke of 60 cm. would mean that the engine is 9 ft. high, which is, however, not impossible, as the submarine has a generous beam to give her the cargo-carrying capacity so essential in her work.

It is stated that a special adjustment to the fuel-injection valve permits it to be adjusted, when the engine is at a standstill, for each general range of speed, either high or low. Pressure in the cylinders at the moment of fuel injection is from 42 to 45 atmospheres. No trouble from cracked pistons or cylinders was experienced, even though, on the first round trip, the engines are stated to have turned over more than 11,000,000 times.

An illustration in the original article reproduces the only photograph ever made of the engine room of the submarine. That the engines are Krupp is shown by the beveled cylinder heads with fuel-injection valves set in on angle. This is a unique feature of the Krupp motor. It is also apparent from the double valve mechanism that these are four-cycle engines. As this photograph could not be reproduced for technical reasons, another illustration (Fig.4) is given, which the editor has

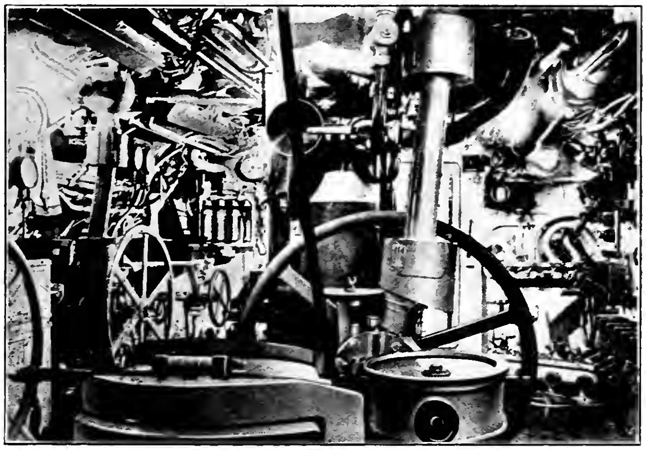

Fig. 4 Central Control Room of the Submarine "Deutschland," Depth Rudder to the Left

been able to secure through the courtesy of Mr. Chas. H. Bedell, Electrical Engineer, Electric Boat Company, Groton, Conn. (*Motorship,* vol. 1, no. 8, December 1916, pp. 3-4, 1 fig. *d*)

A Study of Oil Engines in Iowa Power Plants, H. W. Wagner

Bulletin of the Iowa State College of Agriculture and Mechanic Arts.

The bulk of this Bulletin was written in the early part of 1915 and was based on data gathered before that time. During the interval between the writing and publication, many industrial and commercial changes have occurred, and in particular the price of fuels has changed and the cost of many materials of construction has become abnormal. The Bulletin, however, retains a considerable amount of interest. It covers the use in Iowa of oil engines, carburetion, semi-Diesel and pure-Diesel types, and presents a large amount of valuable statistical material.

It was planned by the Iowa Engineering Experiment Station to secure a list of oil engines in the State, to visit them, and to test some of them, the primary object of the tests being to secure fuel-consumption figures at various loads. For this reason only electric-light and power plants were chosen, as the current from the electric generator offered the most convenient reliable medium for measuring the power developed. Other related measurements were taken, however, such as quantity

of cooling water used, temperatures, indicator cards, and data necessary to calculate a fuel heat balance.

In general it was found that a high-compression or Diesel engine has better fuel economy than the medium-compression or semi-Diesel engine, which in its turn has better fuel economy than the low compression or carburetion engine. The engine with higher compression not only consumes less fuel for a given output of power, but also burns a fuel which costs less per gallon; but its first cost is higher than that of a low compression engine.

Tests on twelve engines of various makes and types showed a fuel consumption per estimated b.hp-hr. ranging from 2.95 to 0.55 pints. Reports of monthly operating records from seven of the most efficient oil-engine plants in the state show a range of from 2.60 to 1.03 pints of fuel oil per kw-hr. generated. Corresponding fuel costs ranged from 1.30 to 0.39 cents per kw-hr. The high figure is taken from a plant containing three carburetion engines with a total rating of 330 hp., burning distillate figured at 4 cents per gal. The low cost is from a plant containing a 225-hp. Diesel engine burning fuel oil figured at 3 cents per gal.

Fuel combustions during tests did not always average as good as guarantees submitted by manufacturers and agents for the same engines at the same loads. Most of these tests were made without any special preliminary adjustments.

Attendance labor is less in small plants when an oil engine instead of a steam engine is employed, and such is also likely to be the case for larger plants when coal is fired by hand. Lighting plants in many towns of about 500 or 600 population are operated by oil engines, and seem to be holding their own in a financial way. The cost of generating by steam under the same conditions might be almost prohibitive. For engines of over 225 hp. capacity, additional experience is necessary to determine whether best final economy is to be reached by Diesel or steam power.

As to reliability, it is stated that the present oil engine of any type is inherently less reliable than the steam engine or turbine, and more skill is required to keep the oil engine running smoothly. Recent installations indicate, however, that power engineers are gaining confidence in the reliability and general advantage of semi-Diesel and Diesel engines for small and medium-sized power plants.

Oil-engine lubrication has presented a perplexing problem in numerous cases. Proper characteristics required by individual engines and possessed by particular lubricants are not well enough known. Some oil engines are cooled by raw well water, which is then run into the waste. Other plants have installed a cooling tower or basin and use the same water over and over.

Practically all oil engines possess a tendency to knock or pound at times.

Difference of final costs with carburetion and semi-Diesel engines is less than might be expected. A lower price per gallon of fuel oil and a lower fuel consumption with the semi-Diesel are partly offset by the lower first cost of the carburetion engine and lower assumed rates of depreciation and repairs. These rates have been assumed on the basis of past performance. It seems likely that, in the future, such rates will be more nearly equal. Broader experience at both the manufacturing and operating ends is leading to better reliability and fuel economy in the semi-Diesel engine. Also increased production is likely to lower the first cost of the latter type. In the above calculations the price of fuel oil for the carburetion engine is assumed at four cents per gallon and that for the semi-Diesel at three cents. The difference is only one cent, but when it is more, as often occurs, the advantage in favor of the semi-Diesel will be increased accordingly.

The Bulletin contains cost figures of operation of various types of oil engines based upon prices existing during 1914 and 1915. A summary of these calculations is given in the following table:

Unit of Energy	Engine Carburetion 50 hp.	Semi-Diesel 50 hp.	Diesel 120 hp.
Brake hp-hr.	2.91	2.75	1.72
Kw-hr. generated	6.60	6.28	3.50
Kw-hr. delivered to line	9.79	9.39	3.50
Kw-hr. delivered to consumers	14.83	14.34	5.78

Consideration of general operating factors, and the actions of manufacturers, then, point to greater future advantages of the semi-Diesel over the carburetion engine than would be indicated by figures in the above tabulation.

In noting the lower energy costs with the Diesel engine, it should be understood that they are due not only to better fuel economy but also to a larger unit and to a greater service demand which eliminates the necessity of a storage battery. Piston and Small-End Lubrication in Diesel Engines, George B. Vickers

Discussion of lubricating troubles in Diesel engines, which the speaker ascribed either to the use of unsuitable lubricating oil or to faulty design.

For Diesel-engine lubrication, pure mineral or hydrocarbon oils are the best, as they contain a much smaller percentage of acid than animal or vegetable oils. Many compound oils are good, but, although they may be carefully blended originally, there is sometimes evidence of disintegration under repeated use. They are also liable to give a gummy deposit. The best test of lubricating oil is on the air compressor. If the oil causes pitting on the compressor valves and shows an acid scouring action on the valves in the air-bottle beds, one may expect the main-cylinder-liner wear to be excessive. As to the amount of the latter, figures taken from a number of engines give a mean wear of 0.010 in. to 0.012 in. per 1000 hours run when the engine is heavily taxed. The lubrication requirements of the small ends and the pistons are contradictory. For pistons, an oil with a moderate viscosity of say 130 to 180 at 140 deg. fahr. gives good results, while an oil with a good viscosity of say 400 to 500 at 140 deg. fahr. is best for small-end lubrication.

For enclosed-type engines thicker oil is required than with the open type, as the temperature inside the crank case is much higher than on open-type engines.

In the works of Hick, Hargreaves & Co., Ltd., a number of naval high-speed engines were constructed and tested under load. With thin oil which had a viscosity of 110 at 140 deg. fahr., difficulty was experienced and the fuel consumption was high. Thicker oil having a viscosity of 140 at 140 deg. fahr. was then used, reducing the consumption from the minimum of 0.45 lb. per b.hp-hr. to 0.419 lb.

A lubricating oil used for pistons or small ends should not emulsify, so that if any water drops in the crank pit it can afterward be separated. When a different oil is used for top-end lubrication than is used for the piston, care should be taken that the oils will blend.

Filtered oil should not be used too often on the pistons, as its viscosity gets too low for this work.

The customary method of piston lubrication is through four or six stems or quills leading through the water jacket to the liner. Many engineers now insist on having a separate feed to each quill, that is, they have a six- or eight-feed lubricator fitted for each cylinder. It is costly but a good plan. Piston seizures have been caused by faulty arrangement of lubricating pipe and leaky back-pressure valves.

Trouble resulted also from improper arrangements of lubricating pumps. In the majority of cases they are driven from the crankshaft and so are placed much higher than the quill line. The result is after a short stoppage the feed pipe has been drained and the piston fails to receive any lubrication for a few minutes after starting. A good plan now adopted by one or two firms is to have the lubricators fixed well below the lubricating belt line and work off the indicator gear on the vertical shaft, thus insuring that the pipes are always charged. The pump should be fitted with a flushing arrangement in case of necessity, and preferably sight feeds with regulating valves. The check valve on the lubricator pipe should be well designed and periodically examined to make sure that there is no bituminous matter holding the valve up and interfering with the supply.

Trouble has been avoided (Mr. Lyle) by altering the piping so that the check valve was vertical and therefore assisted by gravity in keeping on its setting.

The method of securing the quills is sometimes a cause of trouble. Some makers prefer a tapered hole in the liner and provide the quill with a rounded nose: the quill is then screwed home tight over a tapped hole on the water jacket. When the parts get warm and expand, these quills have been found to act as struts and have caused piston seizures immediately opposite to the lubricating holes. An improved method is to have the quill screwed into the liner, a plain hole in the water jacket, and an external joint made. In England a telescopic quill is used.

Some makers have adopted instead of the quill method of lubrication one termed "splash system." With this system the pistons have skirts which protrude well beyond the lower edge of the liner at the bottom of the stroke. The piston relies on the splash from the bottom end of the connecting rod for its lubrication. It was found that this system is effective on pistons up to 14 or 15 in. in diameter, but quite unreliable on larger-type engines. Its chief trouble is that lubrication cannot be regulated, is very uncertain, and there is a tendency to wastage.

Top-End Lubrication. Phosphor-bronze bearings are usually adopted for the top-end bearings, and attempts to use white metal proved unsatisfactory. The wear on phosphor-bronze bearings is seldom more than 0.001 in. per year, while white-metal bearings may show more wear than this in one week. When a phosphor-bronze split bush is used, the average clearance is 0.003 in. vertically and 0.006 in. at each side. More clearance is required if the bush is solid, say 0.006 to 0.008 in. vertically and 0.008 in. at the sides.

The gudgeon pins should be fully case-hardened at the ends as well as on the bearing surface. A case occurred recently where the pin was left soft at the ends, and when tapping the pin into the piston the end of the pin was bulged, and when forced into the piston it split the boss in two places.

The position of the gudgeon pin in the piston is very important. If the pin is located too low, the piston will tend to heel over at the top when maximum compression pressure occurs; similarly, if the point is located too high, the piston will tend to heel over when the maximum working thrust occurs. A good long skirt is advisable to act as a guide and to reduce the pressure per unit area due to thrust. The length of guiding surface on the piston should be 1.4 to 1.6 times the diameter for slow-speed engines, but may be reduced to 1.2 times the diameter for high-speed engines.

The writer proceeds to describe the methods for lubricating the top-end bearings: viz., the scraper system, the banjo system, and the one using one or two slots in the piston which pass over the leads from the oil-supply pipes and hose leading from the bottom of the slots through the piston to the center hole in the gudgeon pin. If this latter method is used, it is preferable to have two slots in the piston, one midway between crankshaft center line and cross center line on the front side of the piston, and one directly opposite, so that whichever side of the liner the piston is thrust against, one of the slots is able to scrape the maximum quantity of oil from the liner. The slot is best when V-shaped in section, and the top and bottom should be undercut at about 45 deg., the scraping edges being left moderately sharp. A sluice should also be cut to connect the top of the slot and a circular scraper groove cut in the piston to take advantage of the oil scraped off the walls by this groove. The slot should be fairly long, but a moderate head of oil should be allowed between the bottom of the slot and the top of the gudgeon pin. The oil hole should have a large countersink both in the piston and also where it enters the pin. The hole in the center of the pin should be at least $1\frac{1}{4}$ in. in diameter for a 6-in. pin, as it acts as a reservoir for the oil. Two holes at least should be drilled from the top of the pin to the center, one close to each end of the bearing surface: these holes may be drilled at 30 deg. to vertical center line. Both these holes should lead into a longitudinal groove on the top surface of the pin. These grooves should have well-rounded edges to assist the oil to escape.

A system of forced lubrication on all of the bearings effectively solves the problem of top-end piston lubrication, but has its disadvantages, as it is thought likely that the piston will receive too much lubrication. The oil is thrown from the bottom-end bearings on to the liner walls, and when the piston is on its suction stroke the slight pressure in the crank chamber tends to force the oil past the relaxed rings, the result being that the lubricating oil is burned, and very peaky indicator cards are obtained, showing a maximum pressure frequently of from 100 lb. to 150 lb. above compression pressure. The high consumption of lubricating oil has retarded the progress of the enclosed type of engine. These difficulties have been overcome, first, by guarding the bottom-end bearings to avoid splash on to liners; second, by preventing the oil from creeping from top-end bearings along the gudgeon-pin keyway on to piston surface; third, by providing scraper grooves on pistons with return ducts to inside; fourth, by dissipating the vapor in crank chamber, this vapor tending to pass the rings on the suction stroke.

The speaker objected to the common method of withdrawing the oil vapor in the crank chamber, which is to take the air-compressor suction or the main-cylinder suction from the chamber. He believes that this causes dirty valves, is wasteful, and in a few cases has proved dangerous. He found that the vapor is most effectually withdrawn by a belt-driven extraction fan; the gases are led to a baffle box, where they are condensed, thus recovering the oil which by other methods is burned.

In the discussion which followed, it was pointed out that when the sulphur content of the fuel oil reaches a certain limit, the sulphur reacts on the lubricating oil, especially if compounded with vegetable oils, and causes a sticky deposit

analogous to vulcanized bitumen, which destroys the lubricating properties of the oil. (Paper read before the Diesel Engine Users' Association; abstracted from *The Mechanical Engineer*, vol. 38, no. 985, December 8, 1916, pp. 439-441. cp)

HEAT-BALANCE TESTS OF AUTOMOBILE ENGINES, Prof. Walter T. Fishleigh and W. E. Lay

The authors show how a demand for better performance and economy and the ever-increasing cost of volatile fuels have emphasized the necessity for thorough engineering work in the successful automobile manufacturing plant.

The paper is based on a comprehensive test of an automobile engine enclosed in a hood similar to that used on the car in normal service, an air blast being directed through this hood of speeds approximating those at which the engine would drive a car with a given gear ratio.

The results from the heat-balance tests at the three operating speeds of 640 r.p.m., 1000 r.p.m. and 1350 r.p.m are shown in Fig. 5. These curves show that the heat that goes into brake horsepower ranges from 8.6 to 19 per cent, and increases at any one speed as the load is increased. The highest value is found for the greatest load taken at the lowest speed. At 6.25 hp. output, which is about necessary on a good level road for propelling the car at 18 m.p.h., the thermal efficiency of the engine based upon brake horsepower is 10 per cent. This means that when an owner uses in his engine $1.00 worth of gasoline, he develops at the flywheel and delivers to the transmission box just ten cents' worth of power. Where the other ninety cents go is indicated by the relatively long ordinates of the other curves.

Heat loss to the cooling water was practically constant at 600 r.p.m. and was about 40 per cent. At the two higher speeds it decreased with increased output.

The percentage of heat dissipated to the cooling air appeared variable at the low speed, while at 1000 and 1350 r.p.m. there was evident a slight decrease with increased output. The heat loss in the exhaust at 640 r.p.m. varied regularly from 26.6 per cent at low output to 18.6 per cent at 20 hp. At the two higher speeds it was relatively much larger with slight increase in output. It appears, therefore, that the trend of exhaust-gas losses is contrary to that of losses to the cooling water.

The fuel consumption per unit horsepower per unit of time at any speed was high at low horsepower output and decreased steadily as maximum output at any speed was approached. Thermal efficiency correspondingly increased at any speed as the output increased. Under maximum output conditions, which constitute an infrequent and unimportant automobile operating range, fuel consumption is relatively low and thermal efficiency relatively high.

Mechanical efficiency at any speed improves with increased load.

The complete heat balance for one run was found to be as follows:

	B.t.u.	Per Cent
Input	368,000	100.00
Output (b.hp.)	50,560	13.74
Cooling water	113,750	30.90
Cooling air	60,600	16.47
Exhaust	139,632	37.94
Total	364,542	99.05
Heat unaccounted for		0.95

The paper describes in detail the methods and apparatus used.

As regards the fields for future developments, the writer believes that probably overcooling at low speed and output, where ample capacity is provided for all extreme demands, has already received some attention, but important improvements can be brought about from an entirely different direction. Alloy metals can be developed that will stand a far higher average operating temperature. The present metal construction can be entirely replaced by a built-up alloy-metal construction that will need no cooling system, or, at best, only an air draft. Porcelain or other heat-resisting substances can be utilized for part or all of the combustion chamber, and better lubricants

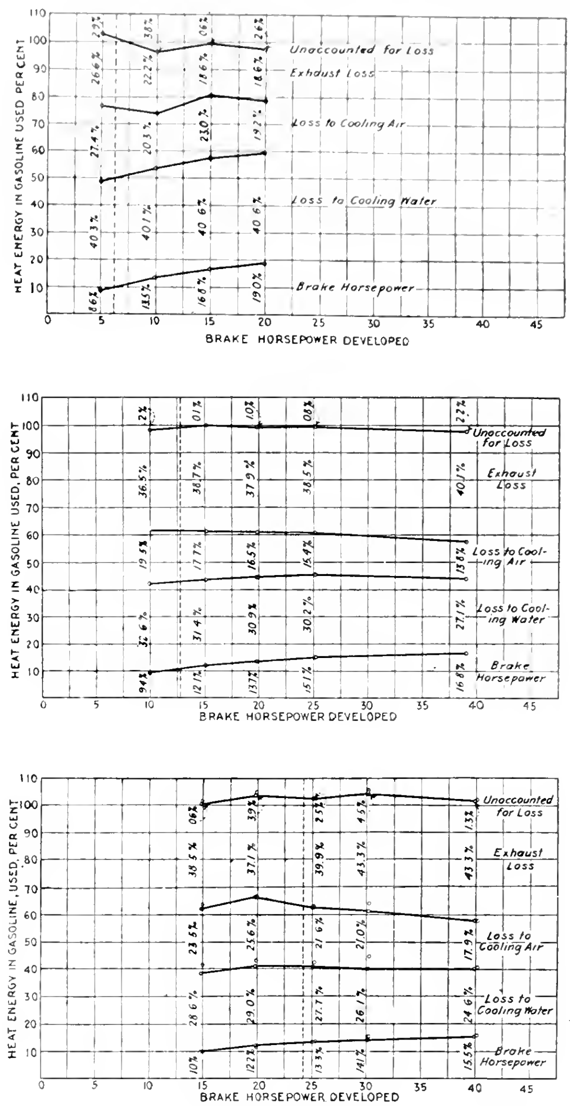

FIG. 5 RESULTS OF HEAT-BALANCE TESTS OF AUTOMOBILE ENGINES AT VARIOUS SPEEDS

are possible. But a fascinating ideal is always a type of engine in which the same wall does not serve as a part of a high-temperature combustion chamber and at the same time as a lubricated surface upon which the most important high-speed reciprocating mass must prevail and have its bearing. Under present limitations higher thermal efficiency might be had by the use of a cooling liquid whose boiling point is higher than that of the conventional water.

The reduced efficiency and increased fuel consumption under normal light loads at any speed are deserving of the most serious attention. The internal-combustion engine op-

erating upon the present Otto cycle is not well adapted to efficient operation upon partly opened throttle, and the author suggests as promising fields of research larger valves or ports and more of them, variable timing of the valves so as to insure fairly uniform compression, higher compressions with direct fuel injection as in the Diesel or semi-Diesel engine, and the constant-pressure cycle. *(S. A. E. Bulletin*, vol. 11, no. 3, December 1916, pp. 271-287, 8 figs., *eA)*

Measuring Apparatus and Measurements

Standard Substances for the Calibration of Viscometers, Eugene C. Bingham and Richard F. Jackson

For the purpose of the calibration of viscometers there is a need for one or more liquids of viscosity greater than water which can be easily obtained in pure condition and whose viscosity is known with a considerable degree of certainty. The substances selected, besides water, were mixtures of ethyl alcohol and water, and sucrose and water. Previous work upon water and alcohol was adequate and consequently the experiments were confined to the sucrose and water. The sucrose was purified by repeated recrystallization from water solution and contained residual impurities of the order of one-thousandth of a per cent. The solutions used in the measurement were analyzed by determination of density and by polariscopic test.

The viscometer used in the investigation consisted essentially of a U-tube fitted with a capillary on one limb surmounted by a bulb with constrictions which could be used to measure the volume of liquid. A bulb of similar size and shape was sealed on the other limb. The viscometer was connected to a manometer and pressure apparatus for the application of pressure. From the observations the viscosity was calculated by the usual formula

$$\eta = Cpt - C' \rho \; t$$

by measuring the time of flow of pure water at 20 deg. cent. and substituting its viscosity 0.01005.

The viscosity was measured at a variety of applied pressures. To obtain the true effective pressure, the height of liquid in the manometer is corrected for air buoyancy, column of connecting air, and hydrostatic head of the liquid undergoing measurement. In order to be certain that the drainage of solution was complete, the time of flow required to discharge and to fill the bulb was measured. Furthermore, viscosity was found to be independent of applied pressure. To test calculations and corrections the viscosities of water were measured, using a considerable range of pressures. The value was found to be constant.

In order to avoid the arbitrary scales of commercial viscometers and the inconvenient magnitudes of the absolute units, we suggest the use of the "centipoise" as a unit of viscosity. This is one-hundredth part of the C.G.S. absolute unit. The centipoise is almost exactly the viscosity of water at 20 deg. cent. (1.005), and hence is at the same time the specific viscosity of any substance referred to water at very nearly 20 deg. cent.

The viscosities of water have been determined by several investigators. The existing data have been reviewed in order to correct them so far as possible according to our present knowledge. The mean values expressed as fluidities may be expressed by the formula

$$\varphi = 2.1482 \left\{ (t - 8.435) + \sqrt{8078.4 + (t - 8.435^2)} \right\} - 120$$

in which φ is fluidity and t centigrade temperature.

Mixtures of ethyl alcohol and water may be used as standards. Their fluidities expressed as functions of temperature and weight and volume percentage of alcohol accompany the complete article.

The viscosities of a 39.99 per cent sucrose solution were measured at temperatures varying from 0 deg. cent. to 95 deg. cent. The observed values correspond to the formula

$$t = 0.597\ (\varphi + 20) - \frac{1438.6}{\varphi + 20} + 38.24$$

Inasmuch as some discrepancy was found to exist between this and former values, the experiment was repeated and practically the same values were obtained.

The measurements were then made on 20.007 per cent and 59.96 per cent sucrose solutions. The fluidities at the latter concentration corresponded to the formula

$$t = 1.472\ (\varphi + 5) - \frac{323.2}{\varphi + 5} + 58.62$$

The values found in the present investigation indicated a higher viscosity than those of previous investigators. (Abstract of *Scientific Paper* no. 298, Bureau of Standards)

Measurement of Flow of Unpurified Gases at High Temperatures by Means of Pitot Tubes, J. M. Spitzglass

During the past year experiments were conducted at the Pitney Court Station of the People's Gas Light & Coke Company of Chicago, on measuring the volume of gas flowing from an individual generator. The device employed, shown in Fig. 6, consisted of a special pitot tube inserted in the flow of gas, connected to a differential gage indicating the pressure difference created by the flow.

As can be seen from the figure, there are here two points available for measuring the flow of gas from the superheater before the gas enters a common main. One is at the outlet from the superheater before the gas enters the washbox, where the average temperature of the flowing gas is about 1200 deg. fahr., and the other is at the outlet from the washbox, where the temperature varies between 180 and 190 deg. fahr., but where there is a possibility of excessive moisture to be entrained from the washbox, the distance from the latter being very short in this case.

As a rule there is now little difficulty in determining the volumes of flowing gases from the velocity pressure developed by the impact of the flow; and the relation between the two physical quantities, velocity and pressure, is well known for ordinary temperatures. But where gases are flowing at high temperatures this relation becomes more or less complicated, as the impact of the flowing mass creating the pressure difference is a complex quantity equivalent to the weight of the flowing mass times the square of the velocity, and the change in the force of the impact may be due to a change in the velocity of the flowing mass or a change in the density of the gas, or to both.

The installations as made proved that the flow of hot gas could be measured in this way and that the high temperature of the gas did not apparently affect the tube or interfere with the indications of the gage. It was found, however, that the tube could not be operated continuously on account of the carbon accumulating and covering the small openings through which the differential pressure is transmitted to the velocity gage. This carbon deposit was found to consist of a layer of lampblack mainly on the side from the flow.

An attempt was made to blow out the tubes with steam with-

out removing them from the gas main, but in many cases it was found necessary to remove them and clean them out mechanically.

Various arrangements of tubes were used with somewhat different results in the flow tests. The one which worked apparently better than other shapes had the ends cut off to a 60-deg. angle from the horizontal.

The results of the tests are presented in charts and tables. One table appended to the article gives the general properties of dry air from 0 to 212 deg. fahr. and also the pressure and density of saturated water vapor. A second table gives the properties and correction factor of saturated gases. This correction factor is independent of the specific gravity of the gas and can be used directly for correcting the volumes of saturated gases at the given temperatures between 0 and 212 deg. fahr. at 30 in. absolute pressure. Other tables give the factors prepared for determining the ratio of the density of atmospheric air at the given temperatures and of gases from 0.75 to 0.40 specific gravity to the density of dry air at 60 deg. fahr. temperature and 30 in. absolute pressure. This "specific ratio" is substituted for the specific gravity of the gas in computing the v lume of the flow.

For the purpose of computing the flow of saturated gases, the writer gives the following equation:

$$Q = 21.7Cd^2\sqrt{\frac{H}{S}}$$

where Q is the quantity of gas in cubic feet per minute flowing through the pipe at the given temperature and pressure; d = diameter of the pipe in inches; C = a numerical coëfficient depending upon the shape of the pitot tube used; H = differential head in inches of water; and S = specific gravity of the gas as referred to air. A numerical example of the application of the formula is given.

The article recommends a method of procedure for the computation of the flow of gases. Among other things is fully covered the question of the use of the correction factor. The tables may be utilized also for other purposes, such as determination of the carrying capacity of pipes for saturated gases and of conditions of partial saturation. (*American Gas Engineering Journal*, vol. 106, no. 1 (whole no. 3069), January 1, 1917, pp. 5-10, 3 figs., *et*)

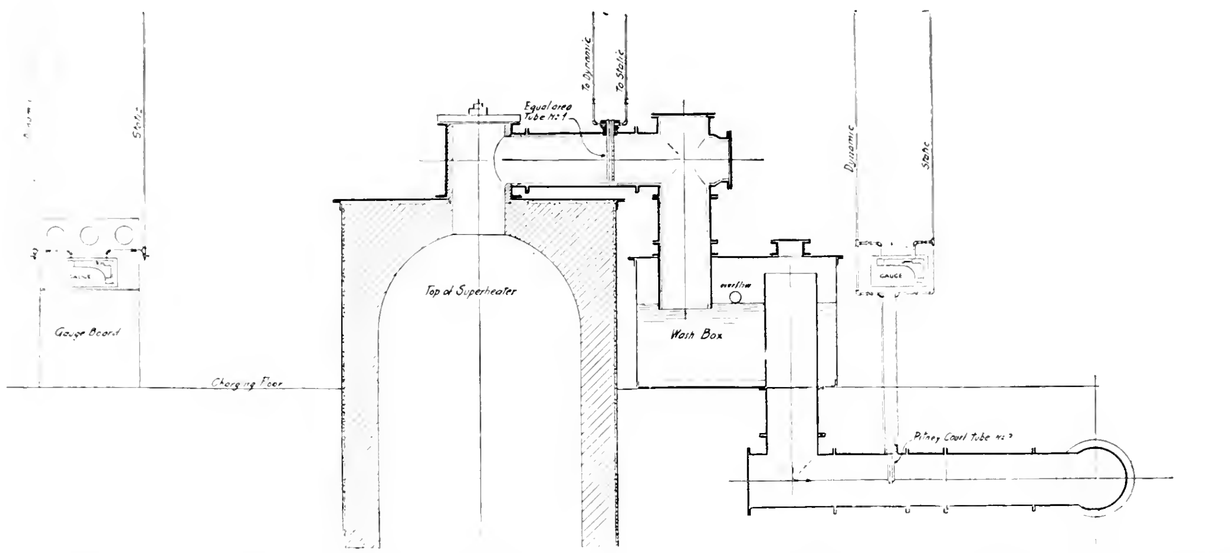

FIG. 6 INSTALLATION FOR MEASURING THE FLOW OF UNPURIFIED GASES AT HIGH TEMPERATURES BY MEANS OF PITOT TUBES

Mechanics

REMARKS ON DYNAMICS OF THE AUTOMOBILE, N. W. Akimoff

Discussion of the fundamental principles of a theory of spring suspension, with a brief consideration of the dynamics of spring damping, kinematic features of harmonic motion, energy consumption, and shock absorbers.

The oscillation of a spring will necessarily be a damped one and will have a tendency to die out after a certain interval of time. This damping is due partly to external friction, but also to a considerable extent to some sort of internal, molecular action. Certain properties of damping oscillations are, however, often lost sight of. If the friction is constant the amplitude of motion decreases but the period remains unchanged. If the damping is proportional to velocity then the period is only slightly increased, but so little that here, too, it can be considered unaffected while the amplitude decreased.

This refers to so-called free vibration of a spring, but a spring subject to any periodic action, for example, actuated by some sort of a connection with an unbalanced engine, will vibrate precisely at the rate of the latter. This constitutes what is known as forced vibration, which the spring quickly converts into a free vibration of its own natural period as soon as it is freed from the influence of the periodic forces. All this, however, holds good only for such cases as that of a spring arranged vertically and supporting a weight, but this formula can under no circumstances be applied to a case of a body rocking about one end and spring-supported on the other. This might induce an error as great as 100 per cent or more, and an entirely new formula would have to be derived.

The writer vigorously objects to applying the plain pendulum formula to cases of automobile suspension involving rolling or pitching.

From the kinematics of vibrating motion can be found under what conditions the passenger will be thrown from a seat vibrating according to a plain pendulum law.

From this the author proceeds to a statement of his objection to frictional shock absorbers. The objection appears to be that in climbing up a bump, the action of the spring is retarded, thus throwing a certain amount of extra load on the tire and spring, already overloaded owing to the upward impulse due to the obstacle. In allowing the compressed spring

to come gently to its normal position, the absorber performs its useful work provided the action is not delayed too much. When the wheel drops into a pocket or depression, the reverse conditions are present. The absorber retards the descent of the wheel and does its best work in restoring the wheel to its normal position, although here, too, the action should not be delayed too much. It is evident that these actions are contradictory. What one would like to have is an absorber that is inert when the wheel goes over a bump and active in coming down, also inert when the wheel goes down into a hole and active in restoring it to its normal position; but it does not appear possible for any absorber to answer these requirements.

The author believes that the fight between the champions and the antagonists of absorbers is progressing on altogether wrong grounds.

The analysis of the elemental suspension system is carried out by means of an imaginary elemental car consisting of one wheel provided with a pneumatic tire, a platform representing the unsprung weight, a spring above it and over the spring another platform, which is the sprung weight. In such a system there will be two independent modes of vibration. One mode will comprise simultaneous oscillations of both weights possessing the *same period*, both moving up or down at the same time. The second natural mode will be such that both weights move in opposite directions although with the same period, but through a much shorter amplitude than before. Neither the short nor the long period is the same as it would be if the sprung weight alone vibrated on its spring. This shows the inadequacy of the pendulum formula if directly applied to the problem of natural oscillations of the car even when simplified in the above way.

The automobile can vibrate in a number of different ways, the main modes of oscillation being plunging, rolling and pitching. The problems of vibrations in automobiles can be solved by Lagrange's equations and, for example, for pitching the author proposes the following formula:

$$\text{Period} = T_p = 2\pi\,(\sqrt{\delta/g}\,\sqrt{2k^2/l})$$

where δ is the initial (static) deflection of each spring under its load; $g = 32.2$; k is the radius of gyration about the center of oscillation; and l the wheelbase. From this formula the author comes to the conclusion that the wheelbase should be kept as short as possible because the period is inversely proportional to its length. From this point of view, the writer believes that if the cantilever arrangement of springs gives better riding qualities, the reason lies in the fact that the spring is fastened more closely to the center of the body, thus giving the same effect as would reduce wheel base, i.e., a slower period of pitching.

The distribution of the weight appears to be of importance, as is evidenced by the radius of gyration k, to which the period is directly proportional. In other words, to secure easy riding (slow period of pitching) the loads should be placed as far as possible from the center of the car. The mere fact that they give the same deflection does not in itself preclude the possibility of entirely different effects due to load distribution. (*S. A. E. Bulletin,* vol. 11, no. 3, December 1916, pp. 262-270, 5 figs, *t*)

Railroad Engineering

Locomotive-Axle Failure and Its Causes

Abstract from the report of the Chief of the Division of Safety, Interstate Commerce Commission, covering the investigation of an accident which occurred near Hoffman, Ill., when an axle failed under a freight engine of the Southern Railroad.

The investigation showed the presence of an area of metal at the surface of the journal which contained chatter marks and short incipient cracks made by the roughing cut in the machining of the forging from which the axle was made.

It was further found that the axle was made from an untreated solid-steel forging and was finished turned throughout its length.

In addition to the discussion of this particular instance, the report touches on some matters of general interest.

Heavy machine-tool cuts tear the metal and also introduce internal strains. There is a close resemblance in the effect of such heavy tool cuts to shearing and punching effects if, indeed, they are not of the same order. Shearing and punching of steel are very properly prohibited in certain specifications, and it is also important that equivalent effects be avoided.

A further possibility of incipient fractures is introduced by the operation of quenching, with spontaneous rupture taking place. In fact, certain specifications with this in view require a shock test to be made of heat-treated axles to detect whether interior fractures have not been made by this process. The final state of internal strain in quenched axles which have had their temper drawn will be of lesser magnitude than the temporary state of strain which prevailed at the time of quenching.

The report emphasizes the necessity of securing workmanship of a high order in the machine finishing and fitting of material which is exposed to such situations as those which are occupied by axles, that is, repeated alternate stresses of tension and compression. While the magnitude of the stresses in the service of axles is somewhat indeterminate, there is no doubt that on some occasions very high fiber stresses are reached. Under these circumstances stresses which are incident to surface conditions should not be augmented by internal strains of fabrication, if they are found to be detrimental.

It has been customary apparently to consider only those stresses in axles which were due to the external loads coming from the weight of the engine or cars, as the case may be. But internal strains at the time of quenching—those which result from heavy machine cuts in rough turning and those which accompany the operation of cold rolling on journals for finishing purposes—appear to attain a magnitude comparable to the direct stresses which are caused by the wheel loads. It is true that such internal strains are mostly those having a tangential direction, while the failures of axles commonly occur by tension in a longitudinal direction, but coincident surface strains of compression have been found to exist in the quenched metal in both tangential and longitudinal directions. (*Iron Trade Review*, vol. 59, no. 26, December 28, 1916, pp. 1309-1312, 7 figs. *dp*)

Steam Engineering

Erosive Effect of Steam on Turbine-Blading Material, Lieut. (J. G.) T. J. Keleher, U. S. N.

In the summer course of the Post-Graduate Department of the Naval Academy an investigation of the erosive effect of steam on turbine-blading material was taken up as a research problem.

The apparatus used was a brass box 9 in. x 9 in x 7 in., which acted as exhaust chamber and contained the brass blading holders and blades, which were stationary and placed at

an angle of 10 deg. to the nozzles in order to avoid the spattering effect. On the front of the box was a steam chest containing expanding nozzles designed for 100 lb. gage pressure and 27 in. vacuum.

Extruded brass, rolled brass, rolled cupro-nickel, monel metal, Parsons metal, and drop forged steel were tested. The tests were preliminary in their nature and will be followed next summer by tests at different steam velocities and with varying qualities of steam and degrees of superheat.

The results are shown in the form of photographs and a table of weight losses. From this table it appears that extruded brass stood up best in the 3400-ft.-per-sec. velocity with steam quality of about 87 per cent. Here the loss was 0.121. Monel metal followed with 0.273 and steel with 0.386.

Because of difficulty in obtaining the blading material there were dissimilarities in the dimensions of the pieces tested, particularly in the case of the steel specimens. These discrepancies in blading width and thickness vitiate weight losses when determined as percentages of the original weights of the specimens. In the case of steel, its width was less, and its thickness considerably less, than that of the other materials.

Rolled brass, cupro-nickel and Parsons metal did not compare at all favorably with the others. In general, there appears to have been no particular uniformity in the amount of erosion during the different periods.

On the photographs (which were taken at about 2 diameters after 3½ hours) can be seen the saw edges of the rolled brass and monel metal, and in particular the long points of the cupro-nickel which, it would appear, are the results of lack of uniformity in the structure of the metal. Steel appears also to begin to develop a similar edge. (*Journal of the American Society of Naval Engineers*, vol. 28, no. 4, pp. 836-838, and 2 pp. of photographs, *e*)

Operation of Curtis Steam Turbines and Alquist Reduction Gears in the Propulsion of Cargo Ships, W. J. Davis, Jr.

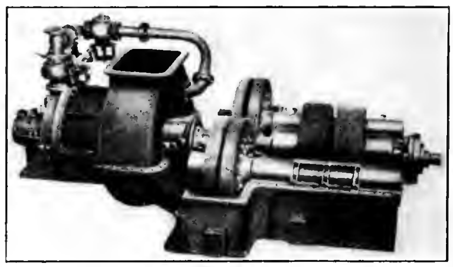
The first commercially successful steam-turbine-driven freighter, the S. S. *Vespasian*, built in England and equipped with a 1000-hp. Parsons turbine with reduction gear, was placed in service in 1909, but it was not until November, 1915, that the first American-built turbine freighter was commissioned.

The first cargo ship built in the United States and equipped with the new drive was the S. S. *Pacific*. This ship was built by the Union Iron Works Company at San Francisco, and propelled by a 2400-hp. Curtis turbine with Alquist flexible gears manufactured at the Schenectady works of the General Electric Company.

The use of the steam turbine in stationary plants resulted in extraordinary reductions in cost of power generation. The writer is familiar with a case where eight 1500-kw. reciprocating engines were replaced by a 12,000-kw. turbo-generator. Whereas it required twenty-four boilers to supply steam for the engines, eleven of these boilers were sufficient to enable the turbine to carry the same load.

It has been well known for a long time that any attempt to drive a ship propeller directly from a steam turbine must result in a compromise in which the efficiency of both turbine and propeller must be sacrificed. In the case of very-high-speed ships, such as destroyers and certain classes of passenger vessels, where certain advantages in the way of increased speed, reduction in vibration and saving in weight overbalance the failure to give the best attainable economy in fuel, it has been possible to make such a compromise. But this would not apply to slow-speed freight-carrying vessels because of limitations of propeller speed.

Take, for example, a freighter or tanker of 8000 to 10,000 tons capacity, with a speed, loaded, of 11 knots. Such a ship will require about 2500 hp. to drive it. The most economical speed for the propeller would be about 90 r.p.m., while that for the turbine would be not less than 3000 r.p.m. The difference is here so great that any attempt to drive the propeller direct would result in an arrangement so greatly inferior in economy to a reciprocating-engine drive as to outweigh any other possible advantage. The use of speed-reducing means between the turbine and propeller becomes, therefore, imperative if turbine drive is to be employed at all. The Alquist flexible gear as manufactured by the General Electric Company is one of the means of high-speed reduction. The wheels for this type of gear are made up of rolled-steel plates or disks rigidly bolted together near the center and keyed to the shaft. Each disk is reduced in thickness between the hub and rim sufficiently to give a small amount of flexibility in an



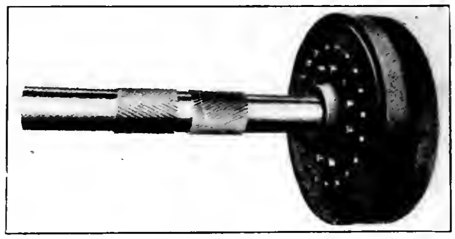


Fig. 7 Top Cut: Upper Half of the Alquist Gear with Gear Casing Removed; Bottom Cut: Intermediate Shaft of Reduction Gear

axial direction, and to permit this movement a clearance of about ten thousandths of an inch is provided between the disks at their rims. As the gears are of the double-helical type, this construction insures equal distribution of pressure along the face of the teeth. If the pressure applied by a pinion tooth at any point should exceed the normal pressure, the axial component will cause a slight axial flexure of the disk. Experience has shown that changes in alignment or slight inaccuracies in tooth cutting or assembling of the gears, which would cause objectionable noise, loss in efficiency, high temperature, and excessive wear on the teeth of solid gears, have little effect on the operation of the flexible-disk type.

Accurate measurements of the teeth of the Alquist reduction gears on the S. S. *Pacific* show the wear of the flexible-gear teeth to be almost negligible.

An interesting commercial feature of the present abnormal production of steel cargo vessels in this country is the uniformity in capacity, speed, and power requirements. Fully 90 per cent of the turbine ships completed or under construction by the Pacific Coast yards are provided with turbines

of the same type and practically of the same size, viz., 2400 to 2600 hp.

In practically all cases the ahead turbine is designed to run at 3380 r.p.m. It is of the Curtis type of impulse turbine and consists of five stages, the first having two rows of buckets mounted on a single wheel, and each of the succeeding stages a single row of buckets. The speed of the turbine is controlled by means of a lever-operated balanced throttle valve in the main steam line, but in order to overcome the loss of efficiency due to throttling when running at reduced speed, two hand valves are provided which block off a number of the first-stage nozzle sections. By this means it is possible to obtain 58, 75, 83 and 100 per cent of full power with full-speed pressure at the nozzles, resulting in a net saving of 3 per cent to 5 per cent in fuel when it is necessary to run the ship at reduced speed in a rough sea.

The astern turbine has two stages of similar construction but of smaller diameter, and is mounted on the same shaft and in the same casing as the ahead turbine, both having a common exhaust. When the ship is running forward, the wheels of the astern turbine revolve in a vacuum and therefore consume but little power.

The speed of the propeller being 90 r.p.m. and that of the turbine 3380 r.p.m., it is necessary to obtain a gear reduction of 37.5. This is accomplished by means of a double reduction, the high-speed gear having a ratio of 7.36 and the low-speed, 5.10. The reduction gear is of the "one-plane" type, i.e., axes of the high- and low-speed pinion and gear shafts lie in the same horizontal plane. This arrangement reduces the head room, simplifies lubrication, and facilitates inspection and accessibility of all parts.

Power is transmitted through the high-speed or driving pinion to two gears, one on each side, and thence through the two low-speed pinions to the low-speed gear. Rigid bearings are used throughout for the gears and pinions. Fig. 7 shows the intermediate shaft of the reduction gear, while Fig. 2 shows the gears with the top half of gear casing removed.

On the score of simplicity it is highly desirable to be able to use the same grade of oil for both the turbine bearings and the reduction gear, thus preventing the duplication of oil pumps, strainers, coolers, storage tanks, settling tanks, etc. It has been possible to accomplish this by the use of a moderate tooth angle and by reason of the flexible-disk construction of the gears. Several grades of oil were tried out on the S. S. *Daranger,* the best results being obtained with a medium-heavy oil having a viscosity of 260 (Saybolt) at 100 deg. fahr., which proved to be right for the dual purpose for which it was used.

The article gives detailed data as to dimensions and fuel consumption of tank steamers *Los Angeles* and *La Brea.* These ships differ from each other only in the character of the propelling machinery and the cargo-pumping systems. The *Los Angeles* is driven by a triple-expansion engine with a propeller speed of 65 r.p.m., and has the usual type of centralized steam pumping plant for discharging her cargo of oil. The propelling machinery of *La Brea* consists of a 2600-b.hp. Curtis turbine with Alquist reduction gear giving 90 revolutions at the propeller. She is fitted with a unique cargo-pumping system originated by O. B. Kibele, Superintendent of Transportation of the Union Oil Company, in which a separate electric-motor-driven pump is provided for each compartment, power being supplied to the motors from a 300-kw. 60-cycle alternating-current Curtis turbo-generator located in the engine room.

Although the average speed of *La Brea* is ½ knot better than that of the reciprocating-engine-propelled *Los Angeles,* it has been found that the increase in fuel consumption of the latter over that of the steam-turbine ship under operating

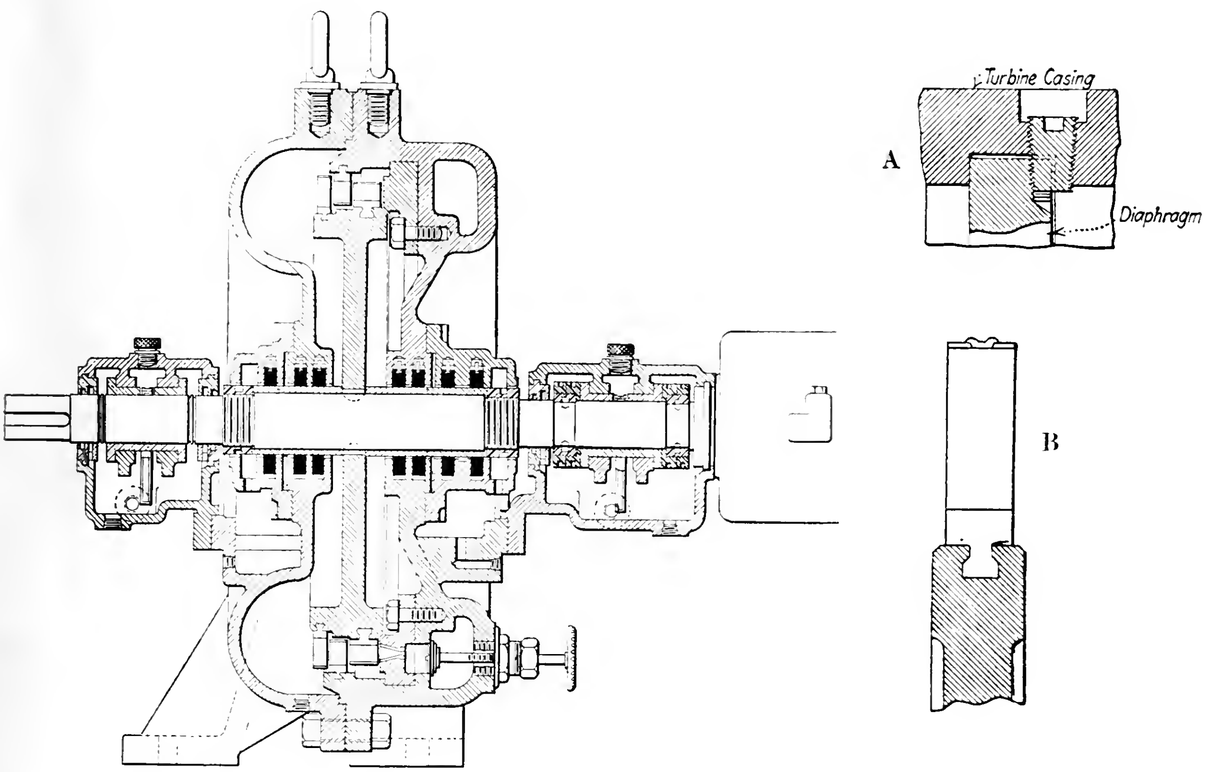

Fig. 8 Moore Steam Turbine

conditions is

While steaming ..17.9 per cent
While steaming and in port......21.1 per cent

With further improvements in the way of increased steam pressures, higher superheats, and power plant design and equipment, there are still further possibilities in reducing operating costs of steamships driven by geared turbines. (*General Electric Review*, vol. 20, no. 1, January 1917, pp. 57-62, 4 figs. *dc*)

The Moore Steam Turbines

Description of steam turbines manufactured by the Moore Steam Turbine Corporation, of Wellsville, New York, a newcomer in this line of production.

The company will manufacture a single-stage machine and a multi-stage turbine. The single-stage machine consists of a single-velocity stage made up of a set of diverging expanding nozzles and a wheel carrying two rows of moving blades with a set of stationary reversing blades following the first row of moving blades. The builders will limit the speed of the larger machines to 3600 r.p.m. and of the smaller ones to 5000 r.p.m. as a maximum.

The multi-stage turbine consists of the same single-velocity stage followed by two or more single-pressure stages, each of the stages consisting of a set of nozzles and a wheel.

In both types of turbine the casings are divided both vertically and horizontally, which allows of lifting the casing without breaking the steam or exhaust connections.

The diaphragms (Fig. 8A) are halved and are held in the casing by a set of special tapered screwed plugs inserted in the vertical joints while the diaphragm and casings are held in a fixture (as a rule in turbine construction dowel pins are used instead of screwed plugs).

The wheels and shaft are of steel and the first-stage wheel is of built-up or solid-forged construction. The wheels of the single stage are machined from solid steel plates. The buckets are of drawn steel and dovetailed into the periphery of the wheel as shown in Fig. 8B. The clearance over the bucket is about one-half inch and the endwise clearance is liberal, with the further provision that the side of the wheel and not the bucket will rub should the rotor become displaced in an endwise direction. (*Power,* vol. 44, no. 25, December 19, 1916, pp. 848-849, 7 figs. *d*)

Willans Line for Steam Turbines

With throttle-governed steam turbines, Willans' law that the total steam consumption plotted against output gives nearly a straight line is followed with very considerable accuracy.

The writer has drawn the Willans line for the 5000-kw. Rateau turbine at the London County Council Power Station from data taken from the paper read by K. Baumann before the Institution of Electrical Engineers in 1911, but used in plotting brake kilowatts and not the power developed at the switchboard. The four points plotted in the diagram, Fig. 9, lie very fairly in a straight line which, if prolonged, cuts the horizontal axis at B. It has frequently been assumed that the distance OB measured on the kilowatt scale represents the power required to drive the turbine light, and that the slope of the line BA is proportional to the blading efficiency of the turbine. The author shows that neither of these suppositions is correct and states further some interesting deductions made from a study of the Willans line of a turbine.

A turbine differs from a reciprocating engine in that by far the larger proportion of its wastes of energy, which are due mainly to windage, leakage losses and fluid friction, are proportional to the load. The resistance and losses which are independent of the load are only those due to the bearings, thrust block, the oil pump and governor drive, and to the glands. If water glands are used, as in the turbine under consideration, the gland losses are represented by the power absorbed by these glands, while if steam-packed glands are used, the loss is represented by the supply of steam necessary to prevent the entrance of air through the glands into the condenser.

The writer calculates these constant losses and shows that this can be done with fair accuracy.

Adding together all of the resistance, he gets a total of 89 hp. or, say, 66 kw., which is only about one-sixth of the distance represented by OB in the diagram, which scales 450

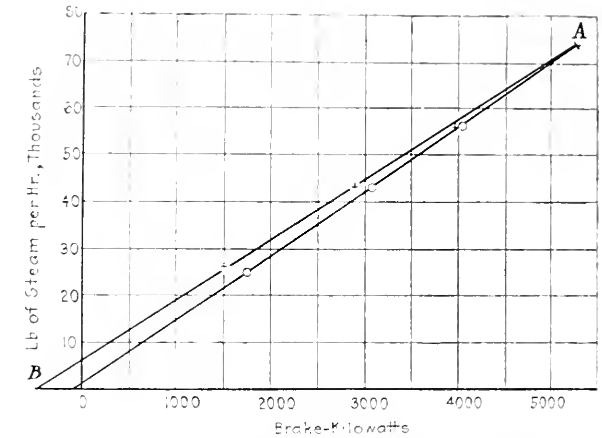

Fig. 9 Willans Line for Steam Turbines

kw. This wide discrepancy is due to the fact that the Willans line BA is not a line of constant indicated efficiency. The indicated efficiency of a turbine varies with the ratio of expansion, and, in many cases, particularly with reaction turbines which (for commercial reasons) have hitherto been run much below the most economical speed, the indicated efficiency at first increases as the load is reduced, afterwards diminishing again somewhat rapidly. It is however possible, to a fair degree of accuracy, to deduce from the actual Willans line a line corresponding to a constant indicated efficiency by making use of the proposition, which is very approximately true, that when a turbine is throttle-governed the indicated efficiency depends solely on the ratio of initial and final pressures. This proposition is necessarily true with a perfect gas, and even though steam is not a perfect gas, the rule holds with considerable accuracy throughout a large range of output.

The data from which the diagram was plotted are as follows:

Output of Turbine, B.kw.	Total Steam per Hour, Lb.	Ratio of Initial to Final Pressure
5347	73,930	228
4000	56,070	185
2885	42,630	123
1449	25,070	74

Of the total resistances of the turbine those due to fan action, leakage and the like are substantially proportional to the load. The fixed resistances have been estimated above as

66 kw., so that the gross output corresponding to the total torque developed at full load will be 5347 + 66 = 5413 kw. Calling this the gross kilowatts the steam consumption per gross kilowatt is 13.66 lb. By the foregoing rule the consumption per gross kilowatt will be the same at all powers, provided the ratio of the initial and final pressures is the same. At the lowest load tabulated above, the initial pressure was 56 lb. absolute and the back pressure 1.55 in. of mercury. To get the same gross efficiency this back pressure should have been approximately $\frac{74}{228}$–1.55 = 0.68 in. of mercury, and in that case the output would have been $\frac{25\,070}{13.66} = 1836$ gross kilowatts, or 1836 — 66 = 1770 b.kw.

This value has been plotted as a round dot in the diagram, and the other observations have been similarly reduced. The corrected Willans line thus obtained cuts the axis at a point sealing about 70 kw., and thus passes very approximately through the estimated value of the bearing, gland, and other fixed losses.

Thus, with the Willans line as ordinarily plotted, the heat available per pound of steam passed falls off as the load diminishes. Hence less work is done per pound of steam and the line at low loads is raised accordingly. The Willans line adjusted as above can be used to estimate approximately the increase in consumption at full load due to reduction in vacuum, and the writer shows that a diminution of vacuum from 28.51 in. to 27.23 in. would reduce the gross output from 5413 to 5100 gross kw., or to 5034 b.kw. Hence such a decrease of vacuum would increase the steam consumption per b.kw.-hour by about 6 per cent. (*Engineering,* vol. 102, no. 2657, December 1, 1916, p. 521. 1 fig. *t*)

Society of Automotive Engineers

The Society of Automotive Engineers is our youngest national technical society. Into it are fused the varied and yet similar and sympathetic interests of the automobile engineer, the aeronautic engineer, the motor-boat engineeer and the agricultural-tractor engineeer. The parent of this organization is the Society of Automobile Engineers, which has been in existence since 1905. Because of the fact that its members are engaged in making very similar products, and because of the tremendous wealth of this one industry, the society has found itself in a unique position to practically enforce coöperation in a technical sense amongst its members.

The outstanding feature that differentiates the S.A.E. from other societies is the stress laid upon standardization. Under the initial guidance of Howard E. Coffin, great progress has been made in the elimination of unnecessary and wasteful variations in unimportant design.

The work that had already been done in the standardization of screw threads was not allowed to stop, but has been carried to a point where lock washers, sizes of steel tubing, steel specifications, fine-thread bolts and nuts, spark plugs, tire bases, magneto fastenings, and so on, have had their important dimensions standardized. This information has been disseminated to all automobile manufacturers and engineers, with the result that considerable labor, time and expense are saved in design by the ability to use what might be called staple dimensions.

The Winter Meeting of the Society of Automobile Engineers, at which the change was made to the Society of Automotive Engineers, was held in the Engineering Societies Building, January 9, 10 and 11, and the following additional standards were discussed, and in the majority of cases approved:

- Direction of engine rotation for aeronautic engines
- Thrust bearings
- Mounting of starting and lighting equipment
- Size of storage-battery jars
- Hand starting cranks
- Size of poppet valves
- V-belts for fans
- Steering-wheel-hub dimensions
- Nomenclature
- Car performance test
- Spring-rebound-clip dimensions
- Pneumatic-tire rims

A sum of $14,000 has been appropriated for the coming year for the work of the Standards Committees, and provided the committees do not run away too strongly with the standards idea, this money will be well spent. There is a tendency to standardize many things which are yet in a transition state, but this is an evil which can easily be overcome, and is indeed usually overcome in itself.

The Standards Committees are usually formed of the chief engineers of the leading companies interested, and one of the features, not the least important, is the opportunity of discussing in an informal way the various problems common to all. This is of material help in advancing the industry and has tended to promote a wonderful feeling of *esprit de corps* and coöperation amongst automobile engineers.

The professional session of the meeting occurred on the afternoon of January 11, at which the following papers were scheduled to be read:

Some Problems in Airplane Construction, Capt. V. E. Clark, Capt. T. F. Dodd, and O. E. Strahlmann
The Ultimate Type of Tractor Engine, H. L. Horning
Dynamic Balancing of Rotating Parts, F. Hymans
Remarks on Dynamics of the Automobile, N. W. Akimoff
Some Essential Features of High-Speed Engines, A. F. Milbrath
Heat-Balance Tests of Automobile Engines, Walter T. Fishleigh and Walter E. Lay
Aerial Navigation over Water, Elmer A. Sperry.

This session was opened by the presentation of a series of unusual stereopticon and motion pictures taken on the various war fronts in Russia, with brief explanations by Capt. V. E. Clark, U.S.A. Aeroplanes, hydro-aeroplanes and captive balloons were illustrated. An interesting feature of the aeroplanes was that, contrary to the general belief in this country, rotary-type motors seem to be very widely used. One of the slides bore the significant statement that 20,000 aeroplanes are used on the French front.

Captain Clark made a statement that the War Department welcomes and seeks the collaboration of the engineers in the development of its technical problems in general and those concerning aeronautics in particular.

Mr. Horning presented orally a general survey of the tractor engine situation. He emphasized very strongly the fact that a tractor engine must be primarily built so that it will run, and those parts which may require renewal or replacement should be designed in such a manner that whenever possible they can be replaced by some makeshift available on a farm.

As a rule the tractor is used in places away from well-equipped machine shops and has to do work which cannot

be delayed. Hence the design of a part may often be influenced quite as much by the possibility of replacement as by considerations of efficiency. As an example of selection on such grounds of expediency rather than engineering efficiency, the speaker mentioned the case of a V belt to drive a fan. It is more efficient than the flat belt, but the farmer may be unable to find it in the local store when needed in a hurry. The flat belt can be easily manufactured out of an old piece of harness, and is therefore used in preference.

The solution of the kerosene engine problem, in the opinion of the speaker, lay in the better-heated intake manifold, and such an arrangement that the heat be increased as much as possible at low speed and reduced at high speed.

Because of lack of time some of the papers were read by title only.

American Association for Advancement of Science

At the meeting of the American Association for the Advancement of Science and the affiliated national scientific societies held in New York City during the last week of the past year, there was a registration in the neighborhood of 2100. The Association met in twelve sections. There were fifty-six separate societies in session, including the four national engineering societies, which held one general meeting with the Association at the Engineering Societies Building. Dr. Henry M. Howe of Columbia University, chairman of the section, presided, and Dr. Bion J. Arnold, the retiring Vice-President and Past-President of the American Institute of Electrical Engineers, gave an address, which was followed by addresses by Mr. Clemens Herschel, President of the American Institute of Civil Engineers, and Dr. Ira N. Hollis, President of The American Society of Mechanical Engineers.

The fundamental idea which was apparently in the minds of the speakers at the meeting of the Association for the Advancement of Science in the Engineering Building, was to properly express the relation of what is commonly known as pure science to engineering as an expression of the so-called applied science.

Dr. Ira N. Hollis, President of the American Society of Mechanical Engineers, expressed on behalf of the engineering profession the most hearty wishes for the continued influence and success of the American Association for the Advancement of Science.

He stated that he had been associated intimately with teachers of science for many years and had never seen one of them engaged in research through which he did not hope to render service either by actually discovering something useful to man or by giving him a true reverence for the Almighty's works, and the last was sorely needed in the present times. Indeed, the speaker stated that if he had to choose he would prefer the rush light with the love of God and his neighbor to the finest electric light with materialism. "We men of science have made the external world what it is, and now we have a most imperative duty not in one or two societies but on the part of all of us, teachers, leaders in science and engineering, to exorcise the Frankenstein that is now trampling the life out of Europe.

"There is no pure science because no man knows the whole truth. . . . We can classify and group related phenomena and we can devise formulæ to express a great range of observation, but they are imperfect and must always remain so. The great function of this Association is something more than a clearing house for science. It must break down the fences that divide science into town lots, and should be freely supported by every engineer and every engineering society.

"It has been proposed that the National Academy and the engineers form some kind of an alliance for research. That would be good, but is not this Association the natural meeting ground for all scientists, and ought not national research to be conducted under the advice of all that the Association can supply?"

The speaker carefully emphasized that there was no distinction between what was called pure science and what was sometimes called applied science. When Theodore Richards was devoting his life to weighing the elements he was accomplishing more for the world than could be found by all the combinations of aniline dyes. In enlarging man's conception of the universe and in supplying him with tools to study it the better, his work was preëminent.

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general; *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society. The Editor will be pleased to receive inquiries for further information in connection with articles reported in the Survey.

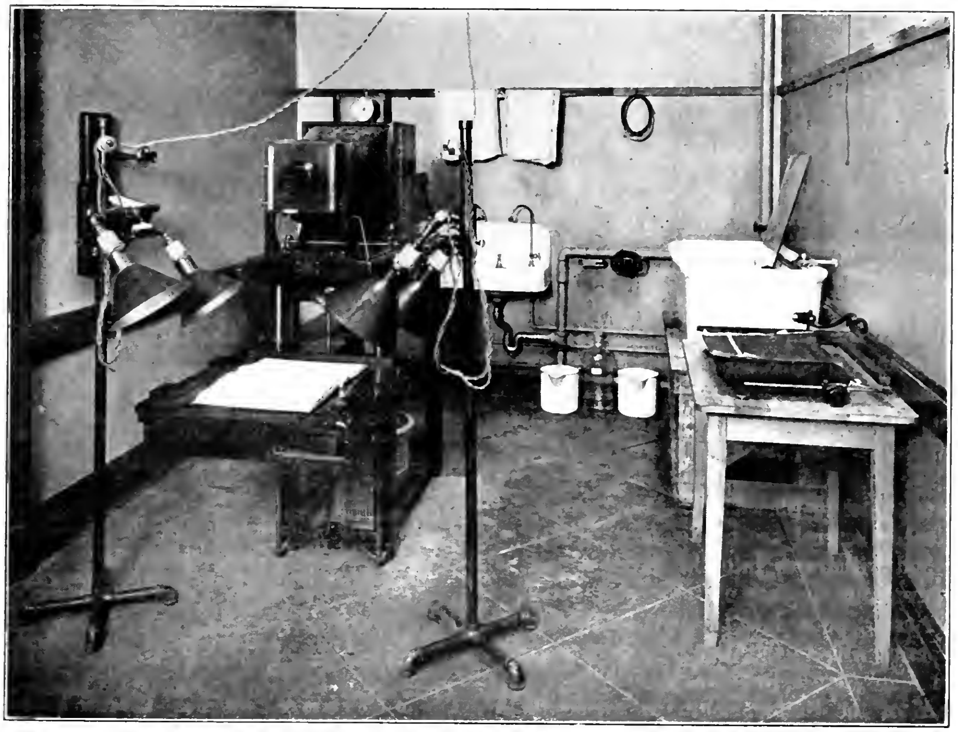
LIBRARY NOTES

From the Library of the United Engineering Society, Engineering Societies Building, New York. Includes Accessions to the Libraries of the Four Founder Societies

Annual Report of Library Board

The Library Board administering the Libraries of the American Society of Civil Engineers, The American Society of Mechanical Engineers, the American Institute of Electrical Engineers and the American Institute of Mining Engineers, maintained as the Joint Library of the United Engineering Society, has just issued its annual report for 1916.

On August 16, 1916, when the American Society of Civil Engineers became a Founder Society, it entered into the same library agreement as the other Founder Societies. Its collection of books, which was started more than forty years ago and contains nearly 90,000 accessions, has therefore been added automatically to the Library of the United Engineering Society. This collection has for many years been a working civil-engineering library and all of the books (with the exception of periodicals) have been thoroughly analyzed and indexed. This library is particularly rich in engineering works of historic interest. It will be most valuable to the engineering profession when merged into the Library of the United Engineering Society, since it will furnish 67,000 entirely new accessions. The books are still in the house of the American Society of Civil Engineers, but will be moved to the Engineering Societies Building within a short time.



Photostat Room in Library of United Engineering Society

The Board for 1916 consisted of

Edward D. Adams	W. M. McFarland
W. P. Cutter	Harold Pender
J. V. Davies	Calvin W. Rice
Karl Eilers	Lewis D. Rights
Alfred D. Flinn	E. F. Roeber
George A. Harwood	Samuel Sheldon
Alex. C. Humphreys	W. I. Slichter
Charles Warren Hunt	Jesse M. Smith
F. L. Hutchinson	E. Gibbon Spilsbury
John W. Lieb	Bradley Stoughton

Leonard Waldo

Messrs. Davies, Flinn, Harwood, Hunt and Rights were added to the Board on October 13, 1916, to represent the American Society of Civil Engineers, which became one of the Founder Societies of the United Engineering Society on August 16, 1916.

Accessions to the Library during the year amounted to 2902 pieces, and the collection totaled, on December 31, 1916, 63,199 volumes.

The Library has received many notable gifts of books during the year. In addition to this, Dr. James Douglas generously donated the sum of \$100,000, the income of which will be used for library purposes as mentioned in the last issue of The Journal.

Quite a large section of the report is devoted to the subject of recataloguing, which the report states must be undertaken in the near future. The necessity for this arises from the fact that when the libraries of the original three Founder Societies were united, their catalogues were assembled so as to form a catalogue of the united collection. The Dewey system had been employed in making each set, but many entries in

the catalogue, requiring judgment, had been determined by at least three different minds from different points of view. The resultant catalogue therefore lacks consistency. The report further states that it would not be wise to undertake this recataloguing before a satisfactory classification has been made of sufficiently broad scope to comprehend the library collection of the future. The report contains a time study of the processes of cataloguing and the determination of the cost to the Library of cataloguing various kinds of books.

Installation of Photostat Machine

Photographic processes for reproducing maps, plates, diagrams, manuscripts and material from printed books, have been in use by engineers and other workers for many years. These processes have been slow and expensive. A few years ago, however, there was developed a machine which makes possible the quick reproduction of such material at a slight expense. Photographs are produced on bromide paper without the intervention of a glass plate.

As will be seen from the illustration, the machine consists of a device for holding the object to be photographed, an apparatus for illuminating the object, and an optical combination of a lens and reversing prism. In addition, a camera capable of adjustment for focusing contains a roll of sensitized paper. The camera box is also provided with a mechanism to rotate the roll of paper, and a cutting knife to be used in separating a sheet of the paper after unrolling and exposure, as well as a manually-operated mechanism for transferring the severed sheet into the developing and fixing pans. The whole apparatus forms one unit. The lighting units are 200-watt Mazda C lamps, supported as shown on special stands.

The book or other object is placed as shown, the camera focused, an exposure of several seconds is made, the sheet rolled off and cut, and withdrawn into the developer; it remains there for the requisite number of seconds, and then is withdrawn through rinsing water into the hyposulphite fixing bath. The whole operation from the time of exposure to the time of fixing is not more than a few minutes.

The Library Board of the United Engineering Society installed in April, 1916, such an apparatus, with proper washing and drying auxiliaries, and has made prints for the clients of the Library Service Bureau during the last nine months of 1916.

This apparatus makes it possible to furnish anyone at a distance with an exact copy of any article in a technical periodical, including text illustrations, maps and diagrams, and thus renders, in connection with reference lists, the resources of the Library available to anyone within reach of the world's mails.

A charge is made to cover cost of labor, materials and current, which is figured at twenty-five cents per exposure.

PERSONALS

In these columns are inserted items concerning members of the Society and their professional activities. Members are always interested in the doings of their fellow-members, and the Society welcomes notes from members and concerning members for insertion in this section. All communications of personal notes should be addressed to the Secretary and items should be received by February 16 in order to appear in the March issue.

CHANGES OF POSITION

David B. Clark, until recently with the Providence Engineering Works, Providence, R. I., has become superintendent of the American Shoe and Foundry Company, Erie, Pa.

John W. Clark, until recently associated with Hodenpyl, Hardy & Company, Inc., Jackson, Mich., has accepted a position with the Central Illinois Light Company, Peoria, Ill.

Frank E. Bardrof has resigned his position with the Pennsylvania Railroad, and is now connected with the Corning Glass Works, Corning, N. Y., in the capacity of machine designer.

Grandon D. Gates has become affiliated with The Celluloid Company of Newark, N. J. He was formerly connected with the A. Y. McDonald Manufacturing Company, Dubuque, Ia.

P. P. Henshall has accepted a position with the Stokes & Smith Company, Philadelphia, Pa. He was formerly instructor of machine shop practice at Pennsylvania State College, State College, Pa.

Edward W. Norris, recently connected with the Southwark Foundry and Machine Company, Philadelphia, Pa., has accepted a position as sales engineer in the New York office of the Mead-Morrison Manufacturing Company.

F. V. McMullin, formerly affiliated with the Pennsylvania Forge Co., Bridesburg, Pa., has assumed the duties of secretary and treas-

ager of the Richter Machine Company, Philadelphia, Pa., which has succeeded the Domestic Machinery Works.

John O. Heinze, who about a year and a half ago formed the John O. Heinze Company in Springfield, O., to make electric starting systems, has severed his connection with the company and has joined the Simms Magneto Company, East Orange and Bloomfield, N. J. He has been appointed engineer and production manager.

Thos. *R. H.* Murphy, formerly member of John H. Wallace and Company, New York, and recently engineer of the Mattagami Pulp and Paper Company of Toronto, has become chief engineer for the Port Arthur Pulp and Paper Company, Ltd., Toronto. Mr. Murphy will be in charge of building the company's 150-ton sulphite mill and 100-ton paper mill at Port Arthur, Ontario.

James A. Norris has assumed the duties of first assistant superintendent of the Presbyterian Hospital, New York. He was formerly connected with the New York Polyclinic Hospital, in the capacity of superintendent.

Robert Shirley, formerly mechanical engineer for the Pratt and Cady Company of Hartford, Conn., and works manager and engineer for The Chapman Valve Manufacturing Company, Springfield, Mass., for the past seven years, has severed his connection with the latter company. Mr. Shirley expects to take an extended vacation before again assuming manufacturing responsibilities.

ANNOUNCEMENTS

H. G. Brinckerhoff has been placed in charge of the Boston office of The Engineer Company.

Miss Kate Gleason of the Gleason Iron Works, Rochester, N. Y., has been elected vice-president of the Trailer Manufacturers' Association, recently formed at Detroit.

Charles B. Rearick, who has been acting as manager of sales for the Covington Machine Company for the past two years, is now located in Covington, Va., as vice-president and manager of the company.

Hugh M. Wilson, first vice-president of the McGraw Publishing Company, Inc., has tendered his resignation and will devote himself to his personal interests. Mr. Wilson has been vice-president of the company for the last six years.

Frederick W. Gay of San Francisco, Cal., announces that he has opened offices as consulting engineer, and will make reports, investigations, appraisals, and design, construct and operate power plants for public utilities and industrial plants.

Fred Ophüls, Halbert P. Hill and J. Harold McCreery, have incorporated under the firm name of Ophüls, Hill & McCreery, consulting engineers. They will specialize on the design and construction of power plants, ice and refrigerating plants and mechanical and electrical engineering.

George C. Hicks, Jr., vice-president and engineer of the P. H. and F. M. Roots Company, of Connersville, Ind., for the past 15 years, announces his retirement from the company on January 1, 1917. Mr. Hicks will act as consulting engineer for the company for a short time. Before taking up work again, he expects to take a six months' vacation.

Charles R. Courtenay, formerly superintendent and chief draftsman with the Watertown Engine Company and late with the New York Engine Company, and Robert E. Cahill have formed a partnership and will conduct business under the name of the Watertown Engine and Machine Company. The company will make a specialty of repairs and replacements to Watertown engines and boilers and, in addition, will do engineering work along the line of testing and adjusting power plant apparatus.

A. W. K. Billings has returned from Barcelona, Spain, where he has been for the past five years as manager of construction, managing director and vice-president of the Ebro Irrigation and Power Company, Ltd., and allied interests, in responsible charge of extensive hydroelectric construction and other work. Previous to his work in Spain and elsewhere for the Pearson interests, Mr. Billings spent two years in Pittsburgh and ten years in Cuba, principally on electric railway and power plant construction, and two years in New York as engineering manager of J. G. White and Company, Inc. He has opened an office as consulting engineer in New York, and will devote considerable attention to work in Europe and in Latin America.

APPOINTMENTS

Henry L. Barton has been made president of the Northway Motor and Manufacturing Company. Mr. Barton has been an executive of the General Motors Company for several years.

John H. Suter, formerly with the Snow Steam Pump Works, Buffalo, N. Y., the St. Joseph and Doe Run Lead Companies in southeast Missouri, and for the last two years with the Western Gas Engine Corporation, Los Angeles, Cal., as shop superintendent, has been appointed chief engineer and general superintendent of the Western Gas Engine Corporation.

Max E. Cutler, chief engineer of works of the Whiting Manufacturing Company, Bridgeport, Conn., has been appointed supervising engineer for Hamilton, DeLoss, Inc., who will erect a new factory immediately, with the intention of manufacturing metal goods and stamping in various kinds of metals. Mr. Cutler will still retain his position with the Whiting Manufacturing Company.

AUTHORS

F. De R. Furman is the author of a treatise on Elementary Cams.

Reginald Trautschold is the author of an article on Internal Spur Gearing, which appears in the January issue of *Machinery*.

J. C. Bertsch has contributed a paper on The Steam Jet Refrigerating Machine to the January number of *The Electric Journal*.

Gano Dunn has contributed an article entitled Professional Unity Among Engineers to the January 6 issue of *Engineering Record*.

Robert E. Cranston is the author of Gold Dredging in 1916, which appears in the January 6 issue of the *Engineering and Mining Journal*.

Advantages and Future of Electric Ship Propulsion, by W. L. R. Emmet, appears in the January 6 number of the *Electrical World*.

The Treatment of Export Inquiries, by Sterling H. Bunnell, is published in the January 4 number of *The Iron Age*.

Frederick C. Moore is the author of A Cost System for a Small Malleable Foundry, which is published in *The Foundry* for January.

An article on the Design of Oil-Ring Bearings by William Knight is published in the January 9 number of *Power*.

J. E. Johnson, Jr. is the author of Technical Advances in Iron and Steel, in the January 4 number of *The Iron Age*.

W. F. Durand has contributed an article to the January 6 number of the *Electrical World* on Progress and Outlook in Prime Movers.

B. S. Nelson of New Orleans, La., is the author of an article on Flow of Air Through Orifices Against Back Pressure, which is published in the January 4 issue of *Engineering News*.

Arthur J. Slade has contributed a paper entitled, What Motor Trucks Offer to Contractors, to the January 6 issue of *Engineering Record*.

Charles E. Knoeppel has contributed an article entitled How Profit-Sharing has Worked in Foundries, to the January issue of *The Foundry*.

B. A. Behrend is the author of The Signs of the Times in Generating Apparatus, which appears in the January 6 number of the *Electrical World*.

Charles A. Stone is the author of an article entitled Engineer's Relation to Foreign Expansion, which is published in the January 6 issue of the *Engineering Record*.

Harry L. Horning presented a paper on Seeking the Ultimate Tractor Engine, at the New York convention of the Society of Automobile Engineers, January 9 to 11.

Lawrence Addicks is the author of Metallurgy of Copper in 1916, which appears in the January 6 issue of the *Engineering and Mining Journal*.

Frederick Hymans presented a paper on Dynamic Balance of Rotating Parts and Dynamic Balancing Machines, at the convention of the Society of Automobile Engineers, held in New York, January 9 to 11.

Peter Junkersfeld, president of the Association of Edison Illuminating Companies, has contributed an article entitled, The Sale of Electric Service in Larger Quantities, to the January 6 number of the *Electrical World*.

G. R. Tuska presented a paper on Recent Developments in Design of Municipal Waste Disposal Plants, at the convention of the American Association for the Advancement of Science, held in New York, December 26 to 30.

HEAT TREATMENT OF WROUGHT-IRON CHAIN CABLE

An Original Investigation of the Causes of the Comparative Weakness of Power-Forged Wrought-Iron Chain, with Results of Experiments Leading to a Method of Heat Treatment for Their Removal

By W. W. WEBSTER[1] and E. L. PATCH[2]

With Foreword by F. G. Coburn, Naval Constructor, U. S. N.

THE following paper on the thermal treatment of wrought iron is a restatement of the graduation thesis on that subject prepared by W. W. Webster and E. L. Patch, Assistant Naval Constructors, U. S. Navy, at The Massachusetts Institute of Technology.

The subject was suggested by the writer, as a result of experience at the U. S. Navy Yard, Boston, Mass., in the manufacture of chain cables for naval vessels. Prior to July 1, 1914, all chain cables for the Navy were manufactured at that yard, by hand, after the fashion of the old English chain-makers, still followed in other chain shops in this country. Experiments had been under way for several years, looking toward a steam-hammer process, and such a process had, at that time, been developed: satisfactory to the extent that it effectively and cheaply welded the chain, but unsatisfactory in that the chain, apparently perfect, would not meet the breaking-strength requirements.

It became suddenly necessary, in July, 1914, to make the process work in order to supplant hand manufacture. The writer, just at that time, came into direct charge of the work. The process seemed to be good, but it was mystifying, indeed, to see apparently perfect chain snap off under test like cast iron. It seemed as if an *addition* to the process was needed, rather than a change; and heat treatment suggested itself. There was no literature available on the heat treatment of either iron or low-carbon steel. In fact, this thesis appears to

Fig. 1 Heavy Pearlite Structure—from Heavily-Shaded Areas in Fig. 5

Presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, December 1916. The paper is here printed in abstract form. Pamphlet copies without discussion may be obtained; price 15 cents to members, 30 cents to non-members.

be the first work of its kind. A number of engineers familiar with the art of heat treatment were consulted by the writer, but none of them knew of any work having been done which would be of assistance.

It was peculiar that *hand* welded chain was successful under test, yet we knew that it was not so thoroughly welded as the *hammer* welded chain. The latter was very thoroughly hammered, too, and kneaded, so that it should be stiff and strong. In this very stiffness the trouble finally was found.

The distribution of stresses in a studded link under tension is such that there are maxima of bending moment at the ends of the axes of the link and maxima of shear at the quarters. It is well known that iron is weaker in shear than in tension. It was observed that the hammer-welded links always failed in the quarters; that while the hand-welded links stretched freely, the power-welded links would not stretch much prior to breaking.

Fig. 5 Section of Burden Iron Etched 30 Minutes

The following hypothesis was then formulated by the writer, to explain the above phenomena: That the hammer-welded link was so stiff that the shearing stress could build up in the quarters to such a degree that the link would fail by shearing, whereas the hand-welded link was soft and ductile enough to deform under the shearing stress, failure occurring later due to a combination of shear and tension when a higher applied tensile load was reached.

There was no pyrometric equipment available; so in the first experiments, which were necessarily crude, the writer gaged temperatures by eye. Test doublets were heated to a temperature believed to be above the upper critical point, cooled in air, and pulled, giving satisfactory results as regards stretch, character of fracture, and ultimate tensile strength. Heat treatment was plainly the answer to the problem.

The writer therefore proceeded to equip a laboratory and to equip the shop for temperature measurement. After some experimenting, a method of heat treatment was evolved which gave fairly good results. But these results were not always consistent, and while the plant was put on a manufacturing basis, still there were very puzzling questions arising. It was considered very desirable, indeed, to find out really why heat treatment was required for power-forged chain and not for hand-welded chain, what the very best heat treatment should be, how much heat treatment wrought iron would respond to, and, in general, to develop working standards for shop practice.

Messrs. Webster and Patch took up the task as their graduation thesis, being assisted in the work later by J. J. Crowe, Physical Metallurgist, who came to the work from the Bureau of Standards by courtesy of the Director, Dr. S. W. Stratton, and of Dr. G. K. Burgess.

F. G. Coburn.

MANUFACTURE OF POWER-FORGED CHAIN

The various operations involved in the process of power-forging chain are briefly as follows:

Shearing. The bar of round stock is rolled from the storage skids on to rollers which guide it through the shears and against the stop which gages the length of the "bolts." After cutting off, the bolts are packed in special baskets for transfer by crane to the scarfing furnace.

Scarfing. One end of the bolt is heated in a special oil furnace for a distance of about a foot and the end is then bent and upset by a single operation in the upsetting machine. During the same heat the bolt is scarfed under a 2500-lb. steam drop hammer, using special steel dies. The "flash" or web is then removed by a trimming press. The operation is repeated for the other end and the bars are packed in baskets for transport to the bending-machine furnace.

Bending. The scarfed link is heated throughout to about 1100 deg. cent. in a special oil furnace, from which it is swung by a special jib crane to the hydraulic bending press. Here it is bent by wiping it around a mandrel having the shape of the inside of the chain link. This operation leaves the links practically closed and it is necessary to pry apart the scarfs with a crowbar in order to thread the links in the chain.

Welding. The link is first preheated, threaded into the end of the growing chain, and the scarfs closed under a heavy hammer. It is then brought to a welding heat of about 1350 deg. cent. in a special oil-burning chain forge and welded on special "dolly dies" under a light hammer (250-350-lb.). To give the link the proper shape it is brought to welding heat a second time and finished in the dies of the heavy hammer (1800-3000-lb.).

Trimming. The last welding process leaves a "drop-forge flash" inside and outside on the welded end of the link, which is trimmed off by hand.

Studding. The drop-forged chain stud, which is inserted to preserve the shape of the link, increase the strength, and prevent kinking of the chain, is held in place with the link on its side under the steam hammer and pinched in place by a light blow of the hammer.

Heat Treatment. This is accomplished by loading the chain on to a steel flat car, which is run into a long annealing furnace fired by oil burners. The temperature is brought evenly to about 950 deg. cent., well above the upper critical point, as determined by the indications of nine base-metal thermocouples distributed about the furnace, one couple being placed in a bolt of iron under the pile of chain on the car. After the

desired temperature has been maintained for 10 minutes the car is hauled out of the furnace and the chain allowed to cool in the air before proofing.

Proofing. Each shot of chain is given a "proof test" with the hydraulic testing machine up to values given in the chain tables. After proofing, each link of the shot is examined for defects, and if unsatisfactory links are found they are cut out and replaced by the repair crews. In addition to the proof test, a breaking test is made on a "doublet" taken at random during the making of each shot. If this does not equal the tabulated standard others are tried on each side, and if they fail the whole shot is condemned. The proofing load is approximately 60 per cent of the breaking load. The tables of stresses are standard with the Navy Department, being based on both foreign and domestic practice.

Painting. Shots which have been proofed and found satisfactory are coated by hauling through a hot bath of asphalt paint, and are then stowed ready for shipment.

PROPERTIES OF STOCK MATERIAL

At present the iron used for the most important sizes of chain is made by the Burden Iron Company, of Troy, N. Y. The Government requires grade "A" American refined iron, puddled from all-ore pig iron, free from admixture of steel or scrap; phosphorus not to exceed 0.10 per cent and sulphur not to exceed 0.015 per cent.

Chemical analysis of Burden iron, made by the chemical laboratory of the Boston Navy Yard from borings taken from several stock bars, gave the following average results:

Carbon	0.10 per cent
Silicon	0.10 per cent
Phosphorus	0.085 per cent
Sulphur	0.008 per cent

Twelve tensile specimens cut from a 3¼-in. bar gave the results summarized below, which are compared with the Government specification requirements:

	Test results.	Specification.
Yield point, lb. per sq. in.	26,100	24,000
Tensile strength, lb. per sq. in.	49,000	48,000
Elongation, per cent	35.5	26
Contraction of area, per cent	50	40

Charpy impact tests of eight specimens averaged as follows, and indicate the difference of resistance to shock due to the direction of the slag fibers:

Longitudinal, 150 ft-lb. per sq. in.
Transverse, 39 ft-lb. per sq. in.

The appearance of the transverse and longitudinal sections of a stock bar, when polished and etched, is shown in Fig. 1, which brings out clearly the outlines of the different bars and slabs, known as grade "B" bars, which were piled together to make up the finished grade "A" bar. Also each grade "B" bar is seen to be made up of well-defined areas of different shades or depths of color, representing the muck bars from which it was rolled.

Under the microscope the heavily shaded areas have a pearlite and ferrite structure, with numerous slag spots (Fig. 5), showing them to be wrought iron with about 0.20 per cent carbon. The more lightly shaded areas indicate less pearlite (Fig. 2), typical of about 0.05 per cent carbon, and the unshaded areas a pure wrought-iron structure (Fig. 3). Metallographic examination was made of specimens cut from three stock bars all of which displayed the same characteristics of segregated carbon; the line between adjacent areas of high carbon content and of low carbon is frequently very sharp, as in Fig. 4.

HEAT TREATMENT OF BURDEN CHAIN IRON

The thermal analysis of the iron, or the determination of its "critical" points, is quite necessary for an intelligent study of its heat treatment. In Fig. 6 are typical heating and cooling curves for Burden iron, which indicate the positions of the critical points. These are commonly designated as, A_1 (recalescence point); A_2 (lower temperature point of thermal retardation and cooling) on heating and cooling; and A_3 (upper temperature point of thermal retardation and cooling).

Table 1 gives the critical points as determined by the curves. For purpose of comparison, average points are given for pure

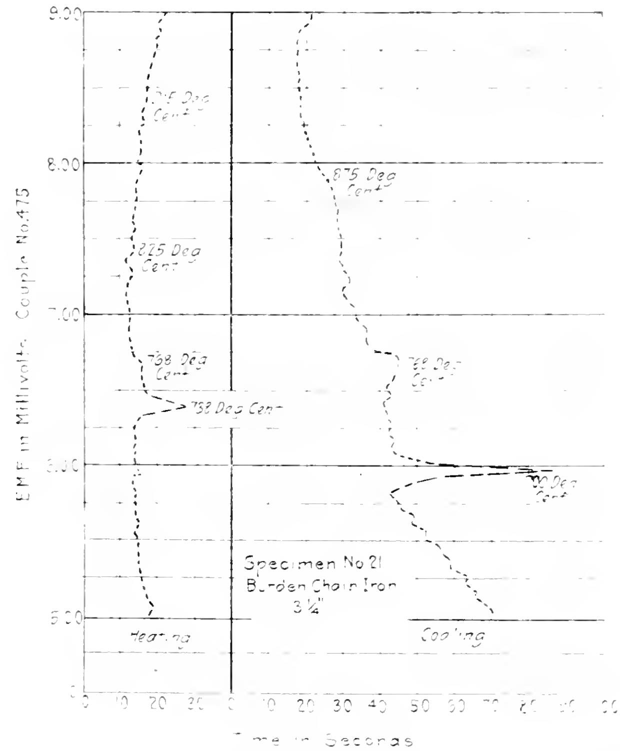

Fig. 6 Typical Heating and Cooling Curves for Burden Iron

iron and for iron of 0.10 per cent carbon and 0.20 per cent carbon, taken from Sauveur's diagram of iron-carbon alloys.

TABLE 1 CRITICAL POINTS FROM HEATING AND COOLING CURVES FOR BURDEN IRON

Critical Point.	Burden stock. Heating, deg. cent.	Burden stock. Cooling, deg. cent.	Average of Heating and Cooling, from Equilibrium Diagram. Pure Iron, deg. cent.	0.1% C, deg. cent.	0.2% C, deg. cent.
A^3	915	875	900	850	800
A^2	768	768	768	768	768
A^1	738	700	690	690	690

In the heating curve, which is the important curve in connection with heat treating, the indication of the upper critical point, A_3, is indistinct and, at first glance, apparently indeterminate.

But the small point shown at 915 deg. cent. was duplicated in size, shape, and position on all of the curves taken; as were also the indications of changes shown by irregularities of the curve from about 825 deg. cent. up to 915 deg. cent. It may therefore be concluded that the upper critical point is not sharp but extends over the range indicated, with a well-defined end at 915 deg. cent. This phenomenon is explained by the unequal distribution of the carbon in the iron, different parts of which vary in composition from pure wrought iron to 0.2

per cent carbon, as was determined by metallographic examination. The second and lower critical points are well defined at the temperature indicated.

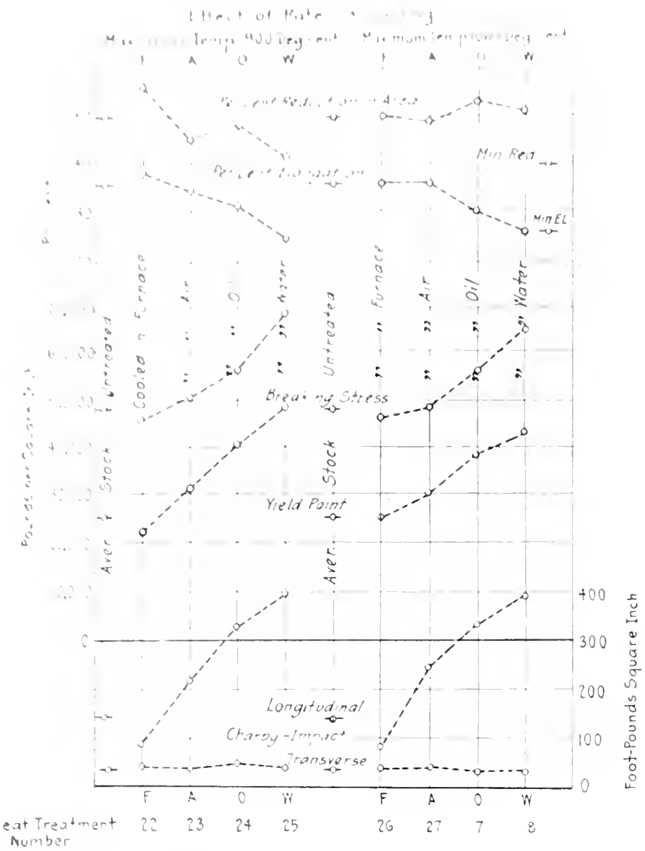

FIG. 7 EFFECTS OF DIFFERENT RATES OF COOLING

Specimens heated to 900 deg. cent. and 1060 deg. cent. cooled in furnace, cooled in air, quenched in oil and quenched in water. Results on untreated material shown vertically at the left and in the center. It may be readily seen: (1) that furnace cooling reduces the Charpy and tensile strength and increases the elongation and reduction of area; (2) that air cooling gives greater strength than the original material with less elongation and reduction of area; (3) that oil and water quenching increase the strength considerably. In the case of heat treatment No. 25 in which the specimens were heated to 900 deg. cent. and quenched in water, the tensile breaking stress was increased from the 49,000 average to 68,700, which is an increase of 40 per cent, and the longitudinal impact resistance was increased from 150 average to 406, which is an increase of 165 per cent. The effect of the rate of cooling on series (*b*), in which the specimens were heated to 1060 deg. cent., was generally less than in series (*c*), in which the heating was carried only to 900 deg. cent.

The practical conclusion from the location of the upper end of the upper critical range on the heating curve at 915 deg. cent. is that to anneal or air-quench the chain from above the critical range it should be heated to about 950 deg. cent., or about 56 millivolts (mv.) on the furnace thermo-couples, instead of 52 millivolts, or 890 deg. cent., as has previously been the practice in the manufacture of wrought-iron chain at the Navy Yard.

LABORATORY EXPERIMENTS IN HEAT TREATMENT

A preliminary study of heat treatment was made in the laboratory for the purpose of securing an indication of the best treatment to be used in the actual manufacture of the chain cable, and the effects of the following variables were studied:

1 Maximum temperature of annealing.
2 Rate of cooling, or quenching.
3 Drawing to different temperatures after heating to maximum temperatures, or after different rates of cooling.
4 Time of annealing, or time material is held at maximum temperature.

The list of heat treatments developed is given in Table 2. Each charge consisted of three tensile specimens and two blocks from which four longitudinal and four transverse Charpy specimens were machined. The furnace was heated to about 750 deg. cent. before specimens were introduced. The temperature was then raised, rapidly at first and slower as the upper limit was approached, to the point where the increase was about 5 deg. in 15 min.

TABLE 2. TABULATION OF HEAT TREATMENTS OF BURDEN IRON STOCK

Series (a): Rate of Cooling.

1 Heat to 900 deg. cent. and cool in furnace.
2 Heat to 900 deg. cent. and cool in air.
3 Heat to 900 deg. cent. and quench in oil.
4 Heat to 900 deg. cent. and quench in water.

Series (b): Rate of Cooling.

5 Heat to 1060 deg. cent. and cool in furnace.
6 Heat to 1060 deg. cent. and cool in air.
7 Heat to 1060 deg. cent. and quench in oil.
8 Heat to 1060 deg. cent. and quench in water.

Series (c): Rate of Cooling before Drawing.

9 Heat to 1000 deg. cent., cool in furnace, reheat to 900 deg., quench in oil and draw to 650 deg.
10 Same as (9) but quenched in water.

Series (d): Maximum Temperature before Cooling.

11 Heat to 800 deg. cent. and quench in water.
12 Heat to 850 deg. cent. and quench in water.
13 Heat to 900 deg. cent. and quench in water.
14 Heat to 950 deg. cent. and quench in water.
15 Heat to 1000 deg. cent. and quench in water
16 Heat to 1050 deg. cent. and quench in water.

Series (e): Temperature of Drawing.

17 Heat to 1000 deg. cent., quench in water, draw to 550 deg.
18 Heat to 1000 deg. cent., quench in water, draw to 650 deg.
19 Heat to 1000 deg. cent., quench in water, draw to 750 deg.

Series (f): Rate of Cooling.

20 Heat to 1000 deg. cent., quench in oil.
21 Heat to 1000 deg. cent., cool in air.
22, 23, 24, 25 Series (*a*) Repeated.
26, 27 5 and 6 of Series (*b*) Repeated.

Series (g): Time of Annealing.

28 Heat to 970 deg., hold 1 min., cool in air.
29 Heat to 970 deg., hold 15 min., cool in air.
30 Heat to 970 deg., hold 30 min., cool in air.
31 Heat to 970 deg., hold 120 min., cool in air.

After the specimens had received their heat treatments as outlined in Table 2, the following tensile and impact tests were made upon the heat-treated specimens:

1 Tensile tests giving
 a Yield point
 b Breaking stress
 c Per cent elongation in 2 in.
 d Per cent reduction in area from 0.20 sq. in.
2 Impact tests giving
 Resistance to shock in ft-lb. per sq. in. of an area of about 0.0785 sq. in. in a bar 10 mm. square by 55 mm. long, with 40 mm. between supports.

All tensile results were within 10 per cent of the average results from the three tensile specimens previously mentioned as having been subjected to heat treatments in each series. The averages are used in all plots.

The Charpy impact results varied greatly; in certain instances as much as 80 per cent from the average. For example, one specimen showed a fine, silky fibrous fracture with 321 ft-lb. per sq. in. resistance, and the next specimen, supposedly from the same bar, a coarse crystalline and dirty fracture with only 39 ft-lb. per sq. in. resistance (heat treatment No. 11).

These variations are probably due to variations in the character of the metal in different sections of the bar, as shown by the metallographic examination. It would be possible even for adjacent specimens to have widely different characteristics, and the probability of this is enhanced by the fact that the breaking sectional area of a Charpy specimen is only about 0.0785 sq. in.

The most important results of the tests are plotted in Figs. 7, 8 and 9.

As a general conclusion from the results of the physical tests, it may be stated that the iron is affected by heat treatment in a manner very similar to low-carbon steel, giving an increase of 40 per cent in the tensile strength and 125 per cent in the longitudinal impact strength when heated to 950 deg. cent. and quenched in water. This was confirmed by microphotographs showing sorbitic and martensitic structure typical of the hardening structure of mild steel.

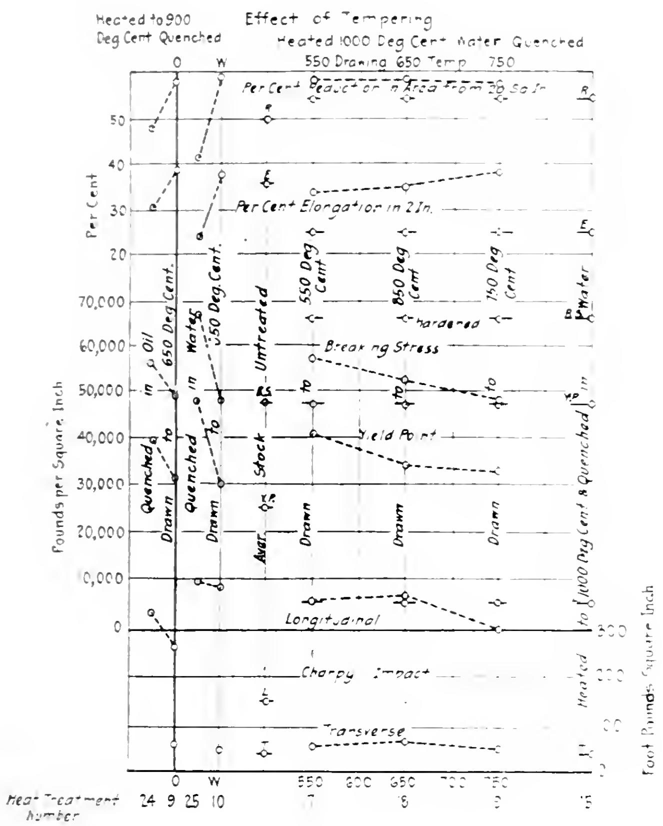

FIG. 8 EFFECTS OF HARDENING AND DRAWING

On the left is shown series (e), the effect of drawing to 650 deg. cent. of specimens heated to 900 deg. cent. and quenching in oil and water respectively. It is seen that the drawing brought the tensile breaking stress and elongation nearly down to the average untreated results, as shown in the left center of the sheet, while the per cent. reduction of area was greatly increased over the average stock results, and the reduction in the Charpy longitudinal strength was very small. On the right is shown series (c) all heated to 1000 deg. and water quenched, the abscissæ being the drawing temperatures, with the results of the undrawn given at the extreme right for comparison. The general effect of increasing the drawing temperature is to reduce the strength and increase the elongation. There is little change in the impact strength and reduction of area, which remain considerably greater than in the untreated stock results.

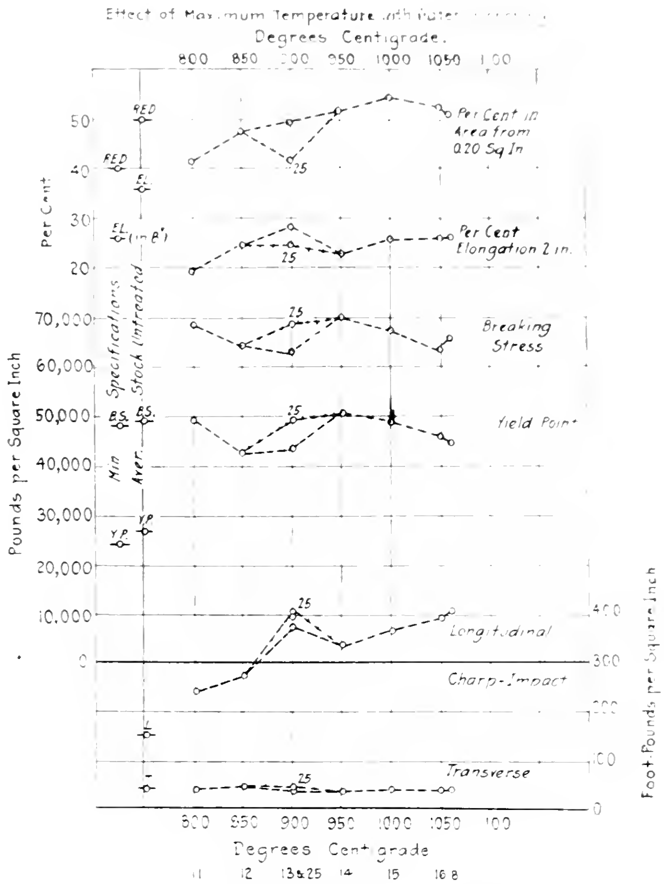

FIG. 9 EFFECT OF MAXIMUM TEMPERATURES OF HEATING WITH WATER QUENCHING

This comprises heat treatments Nos. 11 to 16, inclusive, in which the material was raised to different temperatures and quenched in water; and in addition heat treatments Nos. 8, 13 and 25. The two latter are the same and the difference in the results may be due either to the nature of the material, or to a slight variation in the heat treatment, as apparently there is considerable change near 900 deg. cent. It appears from these results that a temperature of about 950 deg. cent. would give the best results with water quenching and any increase beyond 1000 deg. cent. gives less strength, although the Charpy longitudinal specimens gave best results at 900 deg. cent. and 1060 deg. cent. The data of the oil-quenched and air- and furnace-cooled specimens were not sufficiently complete to warrant plotting.

It is therefore recommended that a further investigation be made of the effect of this heat treatment of chain cable, and the practicability of its application to the manufacture of chain cable.

It was suspected that the length of time during which the specimens remained at maximum temperature in the furnace might have some effect on the results, so a special series (g) was added of heat treatments Nos. 28 to 31, which were all heated to 970 deg. cent. and maintained at that temperature, for intervals of 1 min., 15 min., 30 min. and 2 hr. The results indicated that on specimens of that size the duration of the time of annealing has no appreciable effect.

PRELIMINARY EXPERIMENTS WITH CHAIN LINKS

Two preliminary experiments were performed with full-size chain, (1) to confirm the results of the laboratory experiments as to the best temperature to which the chain should be heated for annealing by air cooling, and (2) to determine the best sequence of annealing and proofing.

It was concluded both from the investigation of the stock material and the laboratory experiments on this subject that the chain should be annealed from about 950 deg. cent. (56 mv.) instead of 890 deg. cent. (52 mv.) as hitherto had been the practice. To confirm this conclusion, 2⅝-in. Burden iron doublets were heated to temperatures corresponding to 48, 52, 56 and 60 mv. The tensile results from the specimens heated to 52, 56 and 60 mv. were not conclusive, but the fractures of the 56- and 60-mv. links, however, were, as a whole, very clean, fine and silky, and much better looking than those of the other links, and the practice has therefore been followed in the

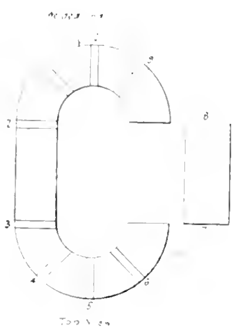

Fig. 10 Location of Test Specimens in Link

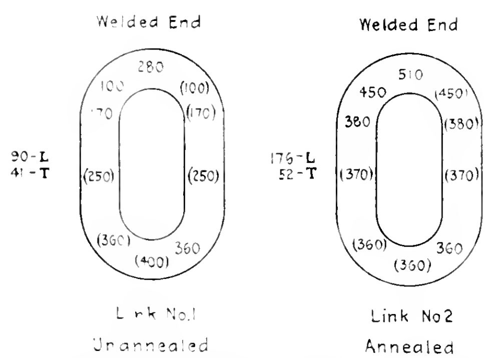

Fig. 11 Grains per Sq. Mm. at Various Sections of Links 1 and 2

manufacture of the chain, of annealing from approximately 950 deg. cent. (56 mv.), with the result that stronger chain has been produced, as determined by the routine test doublets referred to in the second paragraph on p. 193.

The second series of tests, to determine the best order to follow in annealing and proofing, was conducted with 2⅝-in. Burden-iron doublets. Chain may be (1) annealed before proofing, which is the regular practice, (2) annealed after proofing, or (3) annealed before and after.

When chain is proofed, it is strained well over the elastic limit of the link as a whole. For example, 3¼-in. test links are proofed to 367,000 lb., which leaves a permanent set of about ⅜ in. The ratio of proof to pulling load is 367,000: 620,000 = 0.59, while the ratio of elastic limit to ultimate stress of the material is 27,000:49,000 = 0.55.

Proofing therefore strains certain parts of the link above the elastic limit and leaves it in an internally strained condition. If method (1) is used the chain leaves the shop for service with internal strains, but if method (2) is used the internal strains of proofing are relieved by annealing, and from this consideration alone each link should be stronger.

Method (2) appeared to produce the stronger link. On the other hand, it must be noted that four of the six test doublets of method (2) broke by failure of the weld before they were strained to their breaking stress. One of the best men in the shop forged all of the links for this experiment, knowing that they were for experimental purposes. This, combined with the fact that there was only one failure of the weld in the tests made for each of the other methods, indicates that the failure of these four welds was due to the sequence of operations.

The logical explanation is that when a link is proofed before it is annealed there is a tendency to start an opening in the weld due to local strains which may have been produced by forging. Then when the link is subjected to an applied load it will break through the weld before the breaking stress of the material is reached. If the link is annealed before proofing, this condition will be relieved.

After four of the six doublets for method (2) broke through the weld, it was decided to run another series of tests on this method, for which purpose eight 2¾-in. doublets were used. Of these, two broke low with a dull, lusterless fracture, indicating overheating. The average of the other six was 504,000 lb., failing generally across the welded quarter with a fibrous fracture. In spite of the careful welding, the point of the scarf in one link was found not welded when pulled to destruction.

These results were compared with results from tests on 2¾-in. doublets annealed and pulled in the course of regular shop manufacture. These doublets were treated by method (1) by first annealing and then proofing.

The average pulling strength of six of these links was 482,000 lb., which, compared with the 504,000 of the links treated by method (2), shows that the latter process produces the stronger links, provided there is no injury to the weld due to the action of proofing on local strains.

Because this tendency to injure the weld does exist where method (2) is used, the conclusion was reached that method (1) of annealing before proofing should be followed and not method (2). Theoretically, method (3) would seem to be much preferable to both (1) and (2), since it combined the advantages of each, but the average breaking load was the same as for method (1). The fractures, however, were remarkably clean, pure, and silky. There would probably be a small advantage in using method (3), but it is not practical to go to the great additional trouble and expense of two annealing processes for the slight advantage to be gained.

DISCUSSIONS OF WELDING AND ANNEALING

In order to explain the failure of these power-forged, unannealed links and the way in which annealing restored their strength, it is important to understand the essential differences between hand and power forging.

The use of the steam hammer in forging enables a much greater reduction in area to be made at the weld, and hence produces a much greater amount of internal work. It also permits the use of a longer scarf, which necessitates a welding heat further around on the quarter of the link. In power forging, therefore, the link is brought up to a white heat around on the quarter, and then shades off through light orange, dark orange, and bright red, to a dull red at the bent

end. In hand forging the white heat does not cover so large an area and shades down to a dull red on the side of the link, and to black on the bent quarters and end.

It would be expected that these conditions would permit a greater crystal growth of the power-forged chain, except under the hammer at the welded end. Since the welded end of the power-forged link receives a much greater amount of work from hammering, it should have a much smaller grain size than the hand-welded link at the finishing temperature. On the other hand, the power-forged link has a greater cooling range during which the crystals may grow, since its finishing temperature is higher; but most probably this effect is small in comparison with that of hammering. The net results should be an appreciably smaller grain size at the weld of the power-forged link.

In comparison with the other parts of the same link, the grain size at the weld should increase from the middle to the end of the weld as the hammering effect decreases, and then should decrease from the weld around to the bend and in proportion to the maximum temperature to which the part was heated.

Hammering also deforms the crystals at the weld, but this effect should be obliterated by the crystal growth during cooling from 1200 deg. cent. down through the critical range, after hammering has ceased, and there should be no resultant "strain hardening."

The effect of the carbon content should further be considered. Above the critical range, carbon is present in the solid solution of iron, or austenite. As the metal after forging cools slowly in air through the critical range, all the carbon should separate freely from the austenite crystals in the form of pearlite. Therefore, carbon should have little hardening effect in either hand- or power-forged chains; and, since there is no practical difference between the cooling conditions of the two, it should cause no difference between them in hardening.

The only remaining difference between the structures of the hand-forged and power-forged links which could cause the greater stiffness of the latter, is in the grain size. In the side of the link where most of the stretching takes place, the grain size is probably somewhat greater in the power-forged link, while in the welded quarter, where the first power-forged links broke, the difference is probably not appreciable. According to Rosenhain, coarse structure generally does not affect tensile strength or ductility to a marked degree, although it does greatly decrease resistance to shock.

Therefore, from a theoretical consideration of the material as an alloy of iron and carbon only, we can find no apparent cause for stiffness in the power-forging process. In the tests which are hereafter described, however, it developed that in the power-forged link there was an overheated, distorted structure, which was relieved by the recrystallization in annealing. The stiffness of the link was undoubtedly removed primarily by relieving this condition, but also to some extent by the lessened hardening effect of carbon and the refinement of grain size caused by annealing.

TESTS OF FULL-SIZE LINKS BEFORE AND AFTER ANNEALING

For the purpose of testing, a shot of five $3\frac{1}{4}$-in. Burden iron links was forged in the regular manner and four of these were annealed. Specimens were cut from the unannealed link (designated as No. 1) and from one of the annealed links (designated as No. 2). The remaining three links were pulled. Ten sections were located around links Nos. 1 and 2, as shown in Fig. 10. Piece 7-8 was used for tensile specimens and Charpy specimens were cut from the straight section 2-3 and from the curved section 0-1.

A slice $\frac{3}{4}$ in. thick was cut from each of sections 0 to 6, and from 9, for metallographic examination. Eight specimens $\frac{3}{4}$ by $\frac{3}{4}$ by $\frac{1}{2}$ in. were cut from each of these slices, numbered from 1 to 8, and their faces polished as required.

At the time the tests were started it was the practice to heat the chain to about 890 deg. cent. (52 mv.) and this value was used throughout. The present practice, as previously stated, is to heat to 950 deg. (56 mv.). The effect which this change might be expected to have on the results will be discussed later.

It should be noted that the tensile specimens, cut as they were from the side of the link, give a test of the material in that place only, and not of the material in other parts, nor of the strength of the link as a whole. It was impracticable to cut tensile specimens from the curved ends of the link, where the characteristics of the metal are modified by forging and where, also, the links usually fail.

Of the three links which were pulled, one broke across the welded quarter at a stress of 683,000 lb. The requirements for these links are: proof test, 376,000 lb.; and breaking load, 620,000 lb.

The results of the physical tests of the specimens are given in Table 3. In the third column are entered for comparison the results of tests on untreated stock material previously given. However, only a rough comparison can be made between these results and those from link 1, for the reason that in the link specimens there is a curvature of the slag grain with respect to the axes of the specimens, due to the curvature of the link. This curvature probably renders of no significance any difference under 10 per cent. The only marked difference is in the longitudinal Charpy tests, which gave results 45 per cent lower in the case of those cut from the side of the link, due to a combination of the effects of carbon and overheating in addition to curvature. The longitudinal specimens from the quarter gave somewhat lower results than those from the side, due to the effects of greater overheating, greater grain curvature, and larger grain size. The results of transverse specimens, as shown by the laboratory heat treatments, are generally contradictory and unreliable, and are therefore neglected.

TABLE 3 TEST OF UNANNEALED AND ANNEALED LINKS

	Average Results.		
	Link No. 1.	Link No. 2.	Stock Material.
Yield point, lb. per sq. in.	27,900	26,600	26,100
Tensile strength, lb. per sq. in.	47,600	45,500	49,000
Elongation, per cent	37	38	36
Reduction of area, per cent	51	55	50
Charpy tests, ft-lb. per sq. in.:			
Longitudinal, quarter	85	122	150
Longitudinal, side	90	176	
Transverse, quarter	48	41	39
Transverse, side	41	52	

In comparing the results of links No. 1 and No. 2, the question of curvature is of course eliminated, as the specimens from both links were in the same condition. Link No. 2 gives a small decrease in yield point and strength, and a small increase in ductility, which shows that annealing in air has lessened the hardening effects of carbon. Although annealing has also relieved the overheated condition and refined the grain size, these conditions do not have an appreciable effect in increasing the strength as shown by static tests.

In link No. 2 the longitudinal Charpy tests, side and quarter, were increased respectively from 90 to 176 ft-lb. per sq. in. (practically 100 per cent), and from 85 to 122 (almost 45 per cent), showing that annealing has greatly increased the resistance of the metal to shock, due mostly to relieving the

overheated condition and refining the grain size, which have a decided effect on ability to resist shock.

Comparing the results of link No. 2 to those of the laboratory experiment on Burden iron, which received the same heat treatment (No. 23), it is seen that the yield point, tensile strength, and Charpy results are smaller, and the ductility greater in the case of the link specimens. This indicates that a heat treatment applied to actual chain will not have as great an effect in changing the physical properties of the metal as it does when applied to laboratory specimens, on account of the much greater cross section of the link, and of the mechanical treatment which it has received.

Fig. 12 Link 1. Welded End. Ferrite with Traces of Pearlite, Large Grain Size, Slight Distortion

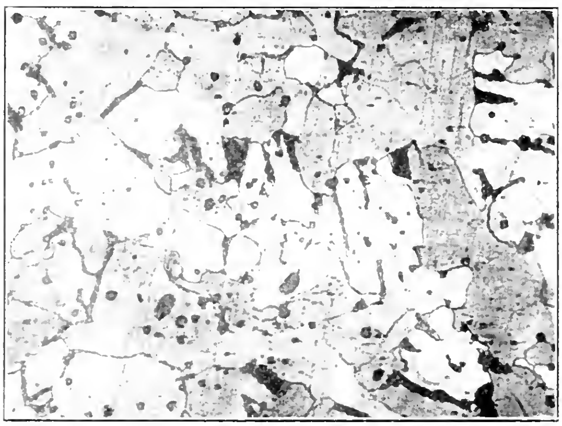

Fig. 13 Link 1. Welded End. Ferrite and Pearlite (0.1 Per Cent C). Medium Grain Size, Slight Distortion

The foregoing tests lead to the conclusion that the present heat treatment of cooling in air slightly decreases the yield point and tensile strength, increases the ductility, and greatly increases the resistance to shock of the metal of the forged link.

GRAIN SIZE OF ANNEALED AND UNANNEALED LINKS

It was desired further to study the effect of the heating and hammering processes and of annealing upon the grain size of different sections of the links.

The average grain size for four of the metallographic sections of the link was estimated by the method of counting grain size which was described and recommended by Jeffries, Kline and Zimmer.[1] The results from links 1 and 2 are as follows:

Section	Link No. 1.	Link No. 2.
0	280 gr. per sq. mm.	510 gr. per sq. mm.
1	100 gr. per sq. mm.	453 gr. per sq. mm.
2	169 gr. per sq. mm.	388 gr. per sq. mm.
6	359 gr. per sq. mm.	365 gr. per sq. mm.

It is not contended that these results are exact. In fact, they are probably not good to within 10 per cent, but it is stated with confidence that they give a very good rough comparison of the grain size of the various sections.

In Fig. 11 are sketches of links Nos. 1 and 2, showing the

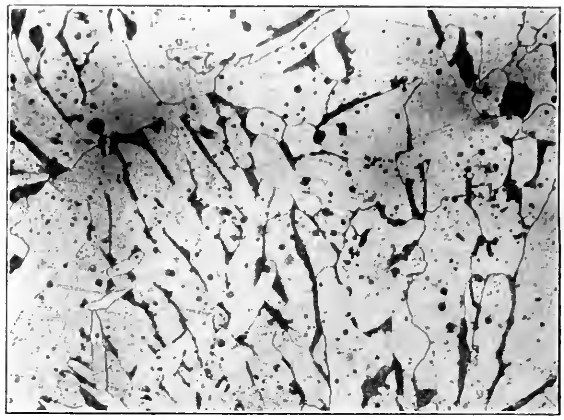

Fig. 14 Link 1, Welded Quarter. Ferrite and Pearlite. Medium Grain Size, Marked Distortion

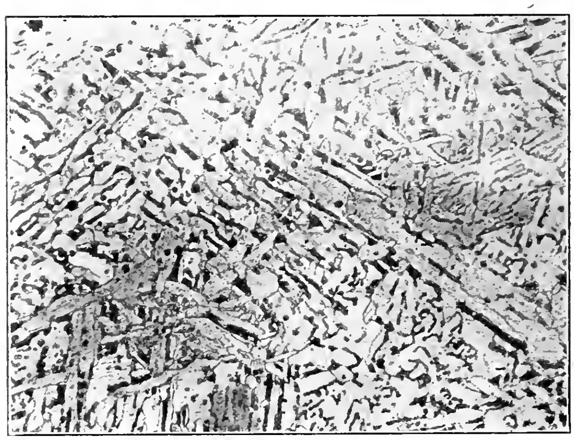

Fig. 15 Link 1. Welded Quarter. Ferrite and Pearlite (0.15 Per Cent C). Medium Grain Size, Marked Distortion with Elongated Ferrite and Pearlite Bands

grain size at the various sections. The determinations in the preceding table are indicated to the closest ten, without parentheses. The other figures, in parentheses, were obtained by induction as follows:

Since both sides of the link are in the same condition by similarity, section No. 9 should be the same as section No. 1, No. 8 the same as No. 2, and No. 4 the same as No. 6, and they are so indicated. The middle of the side of the link should have a grain size about half way between that of the welded and bent quarters, or about 250 gr. per sq. mm. for link No. 1, and 370 gr. per sq. mm. for link No. 2. From the decrease in

[1] The Determination of the Grain Size in Metals: Trans. A.I.M.E., Dec., 1915.

grain size toward the bent end of link No. 1, its grain size at the bent end is probably about 400 gr. per sq. mm. Since there is practically no variation in grain size away from the welded end of link No. 2, the grain size at its bent end is probably about the same as at the quarters, or 360 gr. per sq. mm.

In link No. 1 the grain size is fairly small right at the middle of the weld, but increases rapidly toward the quarter, since the effect of hammering on crystal growth then decreases faster than the effect of heating. But from the welded quarter to the bent end the grain size decreases again; since there has been no hammering and the temperature resulting from heating the link decreases as the distance from the weld.

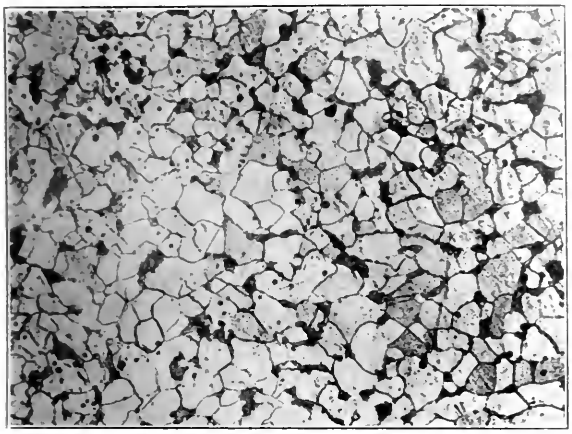

Fig. 16 Link 2, Welded Quarter. Ferrite and Pearlite (0.1 Per Cent C.) Very Small Grain Size

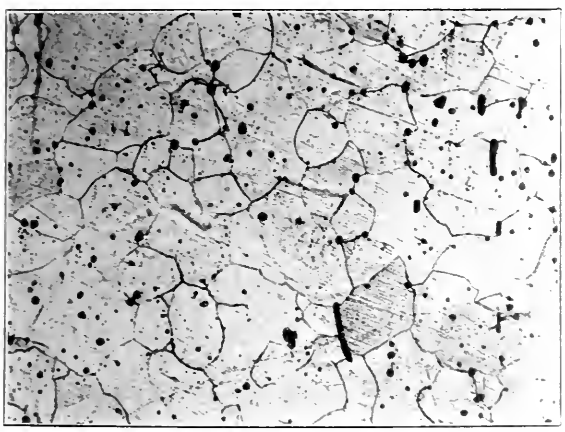

Fig. 17 Link 2, Welded End. Ferrite Structure. Medium Grain Size

Comparing link No. 1 with link No. 2, it is seen that annealing has the effect of refining the grain size of the link, especially at the welded end. This gradation to a smaller grain size at the welded end shows that some effect from the smaller grains in that part before annealing still remains to produce a somewhat smaller grain after annealing, in spite of recrystallization.

CHARACTER OF STRUCTURE OF UNANNEALED LINK (NO. 1)

A microscopic study was made of the structure of the metal and its variation in different sections, and for this purpose both transverse and longitudinal faces of specimens from all parts of each link were examined.

In no section of link No. 1 is the carbon distributed homogeneously; it appears in segregated areas, except that near the boundaries of such areas the carbon has become somewhat diffused into the neighboring ferrite areas due to the various heats which the link had received during manufacture. The proportion of pearlite areas containing greater than 0.05 per cent carbon in different specimens varies from about 15 per cent to about 50 per cent, the average being about 30 per cent.

Typical areas from the welded end containing varying percentages of carbon are shown by Figs. 12-15. The notable feature is the distortion of the ferrite grains into elongated bands with angular bands of pearlite between them. This distortion is proportionate to the amount of pearlite in the area.

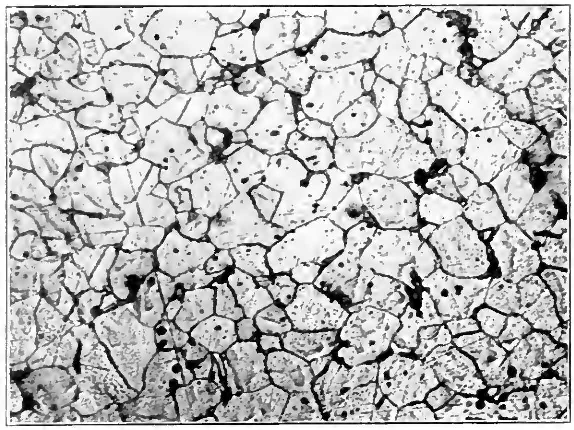

Fig. 18 Link 2, Welded End. Ferrite and Traces of Pearlite. Small Grain Size

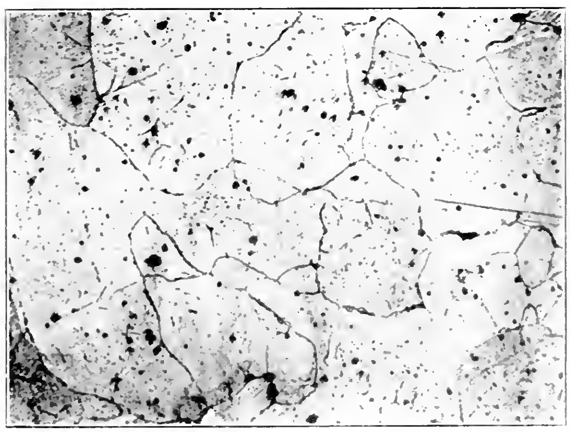

Fig. 19 Link 2, Welded Quarter. Ferrite Structure. Very Large Grain Size

It does not, however, extend through all parts of the welded end. A large number of the specimens at this end show a normal or only slightly distorted structure, and in certain of them signs of slight burning were observed in the vicinity of the weld.

In the other sections of the link, away from the weld, there were no signs of distortion of the grains, and the pearlite had separated from the ferrite crystals in a perfectly normal manner. The smaller average grain size in the bent end of the link was clearly brought out by this examination.

CHARACTER OF STRUCTURE OF ANNEALED LINK (NO. 2)

In the annealed link the same unhomogeneous distribution of carbon was found, as would be expected. Around the

welded end, however, pearlite areas were relatively fewer than in link No. 1, other parts of the link were about the same as link No. 1. The possibility of this non-uniformity between the two links should have been avoided by insuring that both links were made out of the same bar, but the difference was not appreciable enough to affect any of the general conclusions which might be drawn from the experiment.

Typical areas from this link, with varying percentages of carbon, are shown by Figs. 16 to 19. The important point brought out is that there are no signs of distorted structure in any part of the link. The pearlite has separated and segregated around equi-axed grains in the normal manner. The average grain size is fairly uniform but is smaller in pearlite than in pure ferrite areas. Near the weld itself the structure was often very fine, as in Fig. 18, but away from the weld it would grow rapidly coarser, often to a grain size as large as that shown in Fig. 19.

EFFECT OF HEAT TREATMENT

From the foregoing examination, the conclusion is reached that the stiffness of the unannealed link is largely due to the overheated distorted structure in the welded end.

The fact that the metal of the forged link does not return to its normal condition during slow cooling after forging, even if it has been "overheated" to 1350 deg. cent., is probably to a large extent due to the effects of slag and other impurities. Annealing relieves this condition by the process of recrystallization, which practically wipes out all former structure and gives a finer and more normal grain size.

In regard to this overheating, Rosenhain says:[1] " . . . We find that by 'overheating' steel, i.e., by exposing it to unduly high temperatures, or for too long a time at any temperature above Ac, the growth of a very coarse iron structure results, and this, on cooling down, gives rise to a corresponding coarse ferrite-pearlite structure. Not only this, but the arrangement and forms assumed by the pearlite which is formed from such steel is characteristic; there is a strong tendency for the ferrite to take the form of straight bands with elongated and angular patches of pearlite between them, the ferrite bands frequently crossing one another, at angles of 60 deg. Such a coarse, sharply angular structure is, of course, extremely undesirable; there is a minimum of interlocking between ferrite and pearlite, and the straightness of the arrangement facilitates the propagation of slip or cleavage through the crystals. Such structures are, in fact, frequently met with in steel objects which have failed in service. Under test they generally exhibit some degree of weakness as regards shock and alternating stresses, but their tensile strength and elongation are frequently quite satisfactory. The most typical feature, however, is a decided drop in the yield point as compared with that of the same material in a more normal condition."

The above description fits exactly the structure which has been found in the carbon areas of the welded end of the unannealed link. In the results of the physical tests, it was seen that the shock-resisting quality of this link was actually low, but it appears that the tensile strength and elongation are not "quite satisfactory" as indicated in the foregoing quotation.

[1] Introduction to the Study of Physical Metallurgy, pp. 281-282.

CONCLUSIONS

For heat treating, Burden iron should be heated to about 950 deg. cent. (56 mv.) instead of 890 deg. cent. (52 mv.), which was the former practice.

There is no apparent relation between character of fracture and character of structure.

Heating to 950 deg. cent. (56 mv.) for cooling in air gives stronger and better chain than heating to lower temperatures, and heating to higher temperatures gives no improvement.

The present procedure of annealing before proofing should be continued.

Stiffness of the unannealed link compared with the annealed link is mainly caused by overheated distorted structure at the weld.

Annealing removes stiffness of the forged link by relieving overheated distorted structure. It decreases the tensile strength and yield point, and increases the ductility and resistance to shock, of the metal; but it increases the strength, as well as the ductility and resistance to shock, of the link as a whole.

The laboratory experiments indicate the following conclusions:

(1) *Rate of Cooling.*

Cooling in furnace:

Reduces tensile strength from 49,000 to 47,000.
Reduces impact resistance from 150 to 90.
Increases elongation and reduction of area.

Cooling in air:

Increases tensile strength from 49,000 to 50,500.
Increases impact resistance from 150 to 240.
Reduces elongation and reduction of area.

Quenching in oil:

Increases tensile strength from 49,000 to 57,000.
Increases impact resistance from 150 to 340.
Reduces elongation from 36 to 31 per cent.

Quenching in water:

Increases strength from 49,000 to 67,000.
Increases impact resistance from 150 to 400.
Reduces elongation from 36 to 25 per cent.

(2) *Temperature from Which Cooled or Quenched.* Increase of temperature above 950 deg. cent. slightly decreases tensile strength, increases elongation and reduction of area, and does not appreciably affect impact resistance. Temperature of 950 deg. cent. gives best results.

(3) *Drawing Effect.* The higher the drawing temperature, the greater the decrease in tensile strength and increase in elongation. Drawing has little effect on impact resistance.

(4) *Increased Time of Annealing* slightly decreases tensile strength, and slightly increases elongation, reduction of area, and impact resistance.

SIX YEARS' DEVELOPMENT OF THE WERKSPOOR MARINE DIESEL ENGINE

By THOS. ORCHARD LISLE, NEW YORK, N. Y.

Member of the Society

THIS company has completed 37 propelling engines for 24 sea-going mercantile ships, representing about 36,000 hp. Werkspoor was one of the first firms to build Diesel-type engines on an extensive scale. Our first attempt at building the machinery of motorships was most modest. It was recognized that problems would arise which no ship tests or stationary-engine experience could foresee. Throughout we have remained steadfast adherents to the four-stroke cycle and have no reason to regret it. We also decided that unless an engine can be repaired in any port where steam engines can be repaired, it is of no use for ocean-going ships; consequently there is nothing fantastical about our designs, they are exactly similar to an ordinary steam engine.

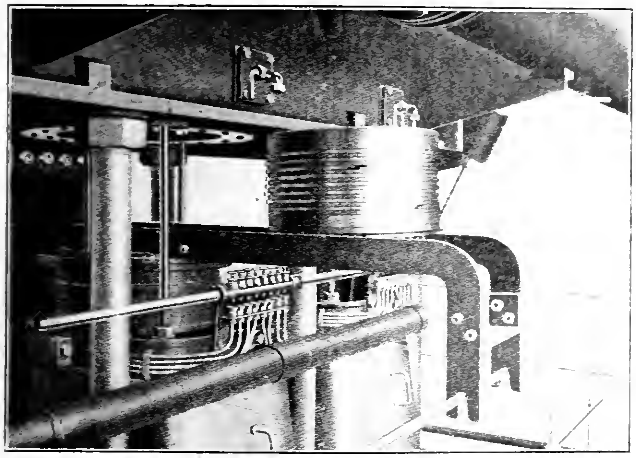

Fig. 1 Improved Method of Removing and Replacing Piston (Patented)

It was the *Vulcanus* that gave us the real experience, as this was the first sea-going full-powered ship, and her engine was the first Diesel to have short pistons, crossheads and guides. She is a ship of 2080 tons displacement and 1235 tons deadweight capacity fitted with a six-cylinder direct-reversible Werkspoor crosshead engine of 450 b.hp. at 160 r.p.m. Her fuel consumption did not exceed two tons per day, or one-fifth of the coal consumption of a steamer of similar cargo capacity. She was placed in service in 1910. At the beginning, trouble was experienced partly through lack of experience of the ship's engineers and partly through her air compressors, but the engines gave very little trouble indeed, wear and tear of the moving parts being very slight, and less than is usually found with marine steam engines. After two years' wear the cylinders were opened up and gaged as shown in Table 1.

On one occasion a high-pressure air reservoir burst while the engines were being overhauled at Amsterdam. Bad welding had left a fracture and the top part of the compressed-air bottle blew off. The indirect cause was the accumulation of water in the air retainer, which had not drained owing to a cracked internal pipe. This mishap taught us to dispense with the welded-type air bottles, also to suspend high-pressure bottles with covers and valves downward, thus effectually preventing any unknown accumulation of water.

TABLE 1 GAGING OF MAIN MOTOR CYLINDERS OF THE "VULCANUS" AFTER TWO YEARS' WEAR

Original Size 400 mm. (15¾ in.)

Cylinder No.	Top.	Middle.	Bottom.
1	400.5 mm.	400.4 mm.	400.1 mm
2	400.6 mm.	400.4 mm.	400.1 mm.
3	400.8 mm.	400.6 mm.	400.6 mm.
4	400.7 mm.	400.4 mm.	400.5 mm.
5	400.6 mm.	400.4 mm.	400.2 mm
6	400.4 mm.	400.3 mm.	400.15 mm.

For several years we have not tested our high-power engines in the shops, but since the war the engines of new ships have had about three hours' running at the wharf and about four hours' at sea. This may surprise some Diesel engineers and probably many will hardly agree with me that a fictitious value has grown round the tests made on the floors of builders' works.

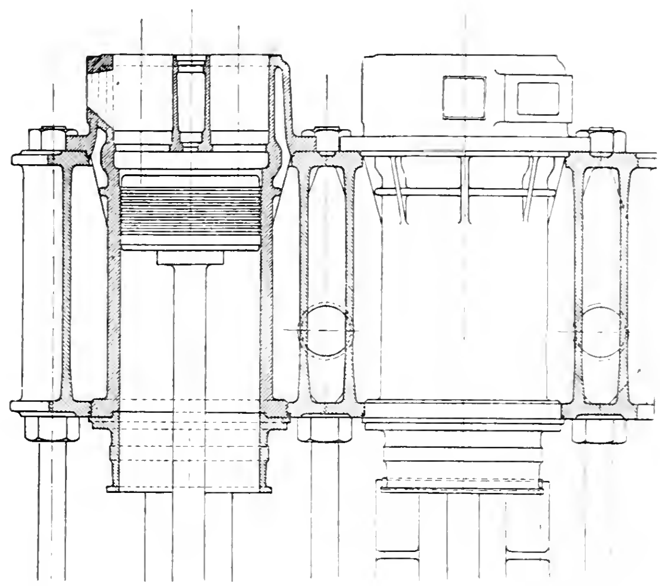

Fig. 2 Section of Cylinder, Illustrating How the Water Cools Hottest Part of Combustion Chamber

Certainly, some of the faults of a new design can be made to appear by shop trials, but when the design has been standardized, the tests are but little more than a check upon the quality of the machine and fitting work.

For years the detachable-cylinder-head design has been the standard practice with virtually every make of Diesel engine both marine and stationary, and still is the recognized standard practice. At the cylinder head, just level with the combustion, that is to say, where cooling is most needed, there are few or no cooling water passages. In the design adopted after the *Vulcanus*, there is therefore a complete water passage round the sides as well as on top of the combustion chamber. Expe-

From an Illustrated Review given at the Annual Meeting of The American Society of Mechanical Engineers, December 1916.

rience with the *Vulcanus* also showed that when using a very heavy oil the rings are apt to become gummed and then stick. So in our next engine, overhauling the pistons was greatly facilitated by the introduction of a patented device by which a piston can be dismounted from below in about 30 minutes, piston rings replaced, and the pistons remounted in about 1½ hours without disturbing any pipes or operating mechanism.

Radical changes in design were made with the engine in the tanker *Juno* in 1912. The frames for supporting the cylinders were entirely dispensed with, and forged-steel columns substituted, stiffening being obtained with and lateral stresses absorbed by diagonal steel rods. The load of tension that these rods have to take is over 130 tons per cylinder, or about 750 tons for the sixteen rods of the whole engine. Although there are cast-iron columns at the back of the engine, they are not secured to the cylinders, but have a sliding-surface fit and carry the crosshead guides; also, being hollow, they are utilized as intercoolers for the air compressors. They allow an up-and-down movement of the cylinders, but side pieces prevent lateral motion.

The open-column construction has been so successful that all our stationary engines are now designed in this manner.

With the later models the fuel-injection valve is offset from the center, and there is at least a space of 4 in. for cooling water everywhere in the cylinder head. Offsetting this valve, in contradiction to all theories, is proving entirely successful in actual practice. As the supporting webs of the cylinders occasionally cracked, our designers dispensed with them entirely in later designs and also improved the shape of the cylinder head. Since these various alterations in cylinder design have taken place, absolutely no cracks have occurred. This engineers will be glad to learn, and it will do much to allay the prejudice that still exists in some quarters against the marine Diesel.

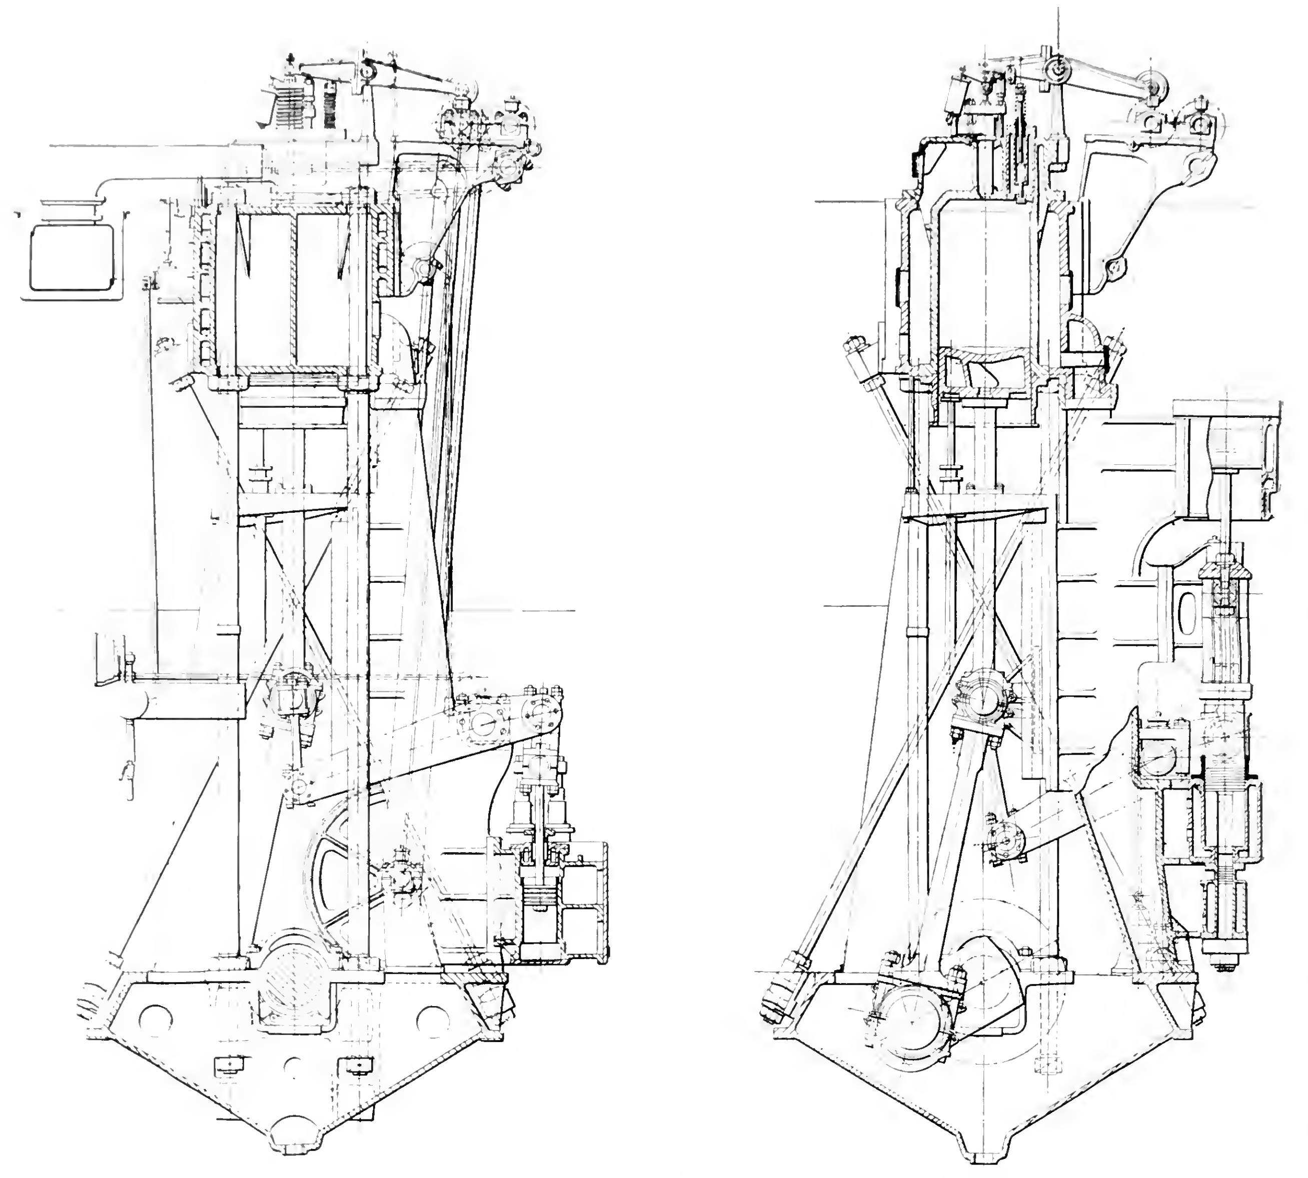

FIG. 3 ENGINE OF THE EMANUEL NOBEL. THIS IS THE TYPE BEFORE THE LATEST IMPROVEMENTS, AS STATED IN THE TEXT, WERE MADE

With regard to piston cooling, all our ships now use sea water for cooling the cylinders, pistons and bearings, there not being sufficient troubles to necessitate a change to fresh-water cooling. With sea water below 100 deg. fahr. practically no scale is deposited. When it is below 70 deg. fahr. it is as good as fresh water. But pistons and cylinders must allow of no

pockets; once scale or dirt starts to deposit, it quickly accumulates and so causes local temperatures.

Our present system consists of a jet of water forced up through clearance tubes, having no rubbing parts, but moving up and down with the piston to prevent splashing. The piston is never more than about half-full of water, the broken surface of the water being far better for the cooling than a solid mass. By means of a simple sight system a chokage of water supply at any point can be detected instantly.

So far as our company is concerned, the trouble with air compressors is absolutely a matter of past history. In the air-compressor system that has replaced the type recognized, the link-and-beam-operation motion is still retained, as this has proved efficient with all the ships. The high and middle stages are arranged side by side, each having its own piston rod, while the first stage is directly below and also has its own piston rod; thus every piston can be separately dismounted. All valves are interchangeable.

In the earlier ships some crankshaft failures have occurred, and crankshafts constructed by the same makers and installed in other ships gave out in the same manner. As a precautionary measure we have lately increased the size of bearings and have installed forced lubrication for the main bearings. For some vessels now building, built-up crankshafts are being adopted.

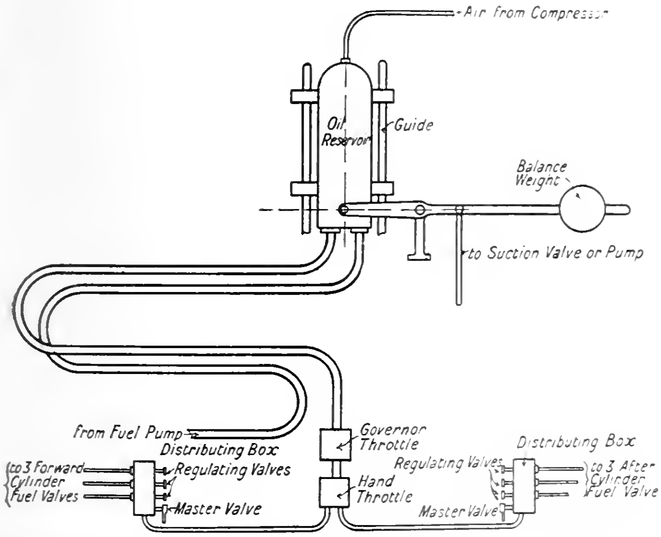

Fig. 4 Fuel-Oil Controlling and Distributing System

A smart ship's engineer can reverse in 5 seconds a 1000-hp. engine from full ahead to astern, but 7 to 10 seconds is the usual time occupied. For the purpose of obtaining the reverse motion there are two camshafts, one for the ahead running and one for the astern movement, and the astern camshaft is driven by means of a spur gearing from the ahead camshaft. These two shafts are mounted on sliding brackets or saddles. When maneuvring, these brackets, by sliding to and fro, bring the ahead or astern cams under the rolls of the valve rockers. By making the rockers unusually large, the angle of the face of each roller, where it meets its cam, is never steep, and this produces smooth and silent running. Thus reversings are rapidly and quietly carried out. The cams and cam rollers are of cast iron, and never have I seen the slightest sign of wear in them, even with a four-year-old ship. The steel tubes have a saw cut down through the center, the two halves being held apart by cross-struts to eliminate vibration.

Most Diesel engines have a separate fuel pump to each cylinder. This method requires too delicate adjustment to supply exactly the quantity of fuel to each cylinder. So a single pump is fitted which supplies two distributing boxes, each box having feeds to three cylinders and every feed its own adjuster. To the exhaust branch of each cylinder is fitted a thermometer by which the engineer can instantly see if any one cylinder is receiving more or less fuel than the others. As a stand-by, an extra pump with a single change-over device is fitted. The fuel pump feeds a reservoir in which an air pressure is maintained, thence the oil passes through a governor-controlled throttle, a hand throttle, and through master valves, and finally into the distributors. The receiver holds enough fuel to run the engine for 15 min., so that in case of a breakdown of the fuel pump the spare pump can be connected up before the engine stops. The distributing boxes are quite close to the indicator cocks, so that adjustment can be made by the engineer in charge while he is reading the cards and thermometers. The plunger fuel pump is made from a solid steel forging; the valves are simply steel balls, and the gland runs in an oil bath. This system was adopted with the earliest ships and has been retained with all since built.

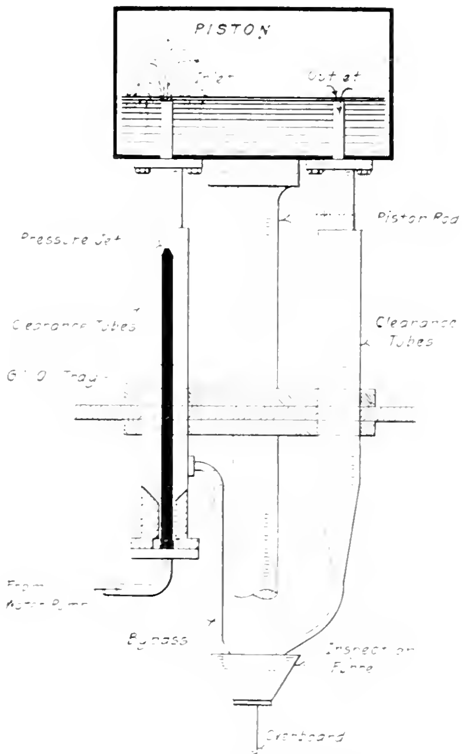

Fig. 5 Piston-Cooling System

At sea the waste exhaust gases of the main engines are utilized to fire a donkey boiler for the ship's auxiliary machinery. This has been most successful and we have since been followed by other shipbuilders. Specially large heating surfaces must be given to the boilers, the temperature being 700 to 800 deg. fahr. compared with 2000 deg. fahr. in the furnace flues of an ordinary oil-fired steam boiler. On the *Emanuel Nobel* and *Elbruz*, sister ships of 6500 tons d.w.c., on a displacement of 9000 tons and with cargo capacity of two million gallons of oil, the auxiliaries are a steam-driven dynamo, a steam-driven spare compressor set, a 7-hp. semi-Diesel, Brons type oil-engine-driven dynamo, and the usual steam-operated pumps. The donkey boiler has two furnaces and the exhaust gases from the two main engines are led

[illegible] furnace and supply sufficient steam for operating the auxiliaries, including the steam gear. The other furnace is used at night for oil-fired burners as, more work being required of the dynamo, not so much steam is available for steering. In the daytime at sea no oil firing is required, for as much as 120 lb. pressure can be maintained with the exhaust gases alone, but usually about 100 lb. is the average pressure maintained. With the *Emanuel Nobel* the recorded fuel consumption for all purposes per 24 hr. day is 9 tons of gas oil — $8\frac{1}{4}$ tons for the main motors and $\frac{3}{4}$ ton for the boiler. This gives 0.29 lb. per indicated horsepower per hour under average running conditions. The total consumption, including auxiliaries at night, works out at 0.32 lb., per indicated horsepower per hour. An oil-fired steamship of the same power would have a consumption nearly four times as great, while an oil-fired steamship of the same cargo capacity and of the same speed ($11\frac{1}{2}$ knots) would have a total fuel consumption five times as great, because her engines would have to be of greater power, owing to the required displacement being about 800 tons greater. Under present abnormal shipping conditions, by the way, the greater carrying capacity of a motorship on a given displacement is even of greater importance than its fuel economy.

With slow-speed, heavy-duty crosshead engines of 200 to 500 hp. at 160 to 200 r.p.m. we have taken a bold step that may make many marine steam and oil engineers shake their heads; but the machinery with which this step has been taken has resulted in being among the most successful of all our installations.

The reversing propeller has been developed and used with four recent full-powered ships, including the *Poseidon*. Several objections may be raised but they will be founded mostly on the prejudice formed by the indifferent services given by reversible propellers, cheaply built and poorly constructed, for the operation of small motorboats. Our mechanism is entirely different. Power to reverse and actuate the mechanism is furnished by the engine itself. By interconnecting the throttle directly with the propeller mechanism, the strokes of the fuel pumps are automatically reduced and increased by the mere act of throwing the blades into the central position, or by reversing them respectively. One important advantage is that the ship can go ahead and astern a hundred times in an hour without the use of compressed air, so that the engine will not be *stalled* at the critical moment owing to lack of starting air. How important this is with a harbor tug can be easily understood. Besides, the navigator on the bridge is given complete control of the ship's movements by a small handwheel installed on the bridge. The reasons for such a radical step may be enumerated as follows:

1 Simplification of main engine due to absence of reversing features
2 Reduction in power and quantity of auxiliary machinery
3 Rapid and independent maneuvring
4 Reduction in first cost of machinery.

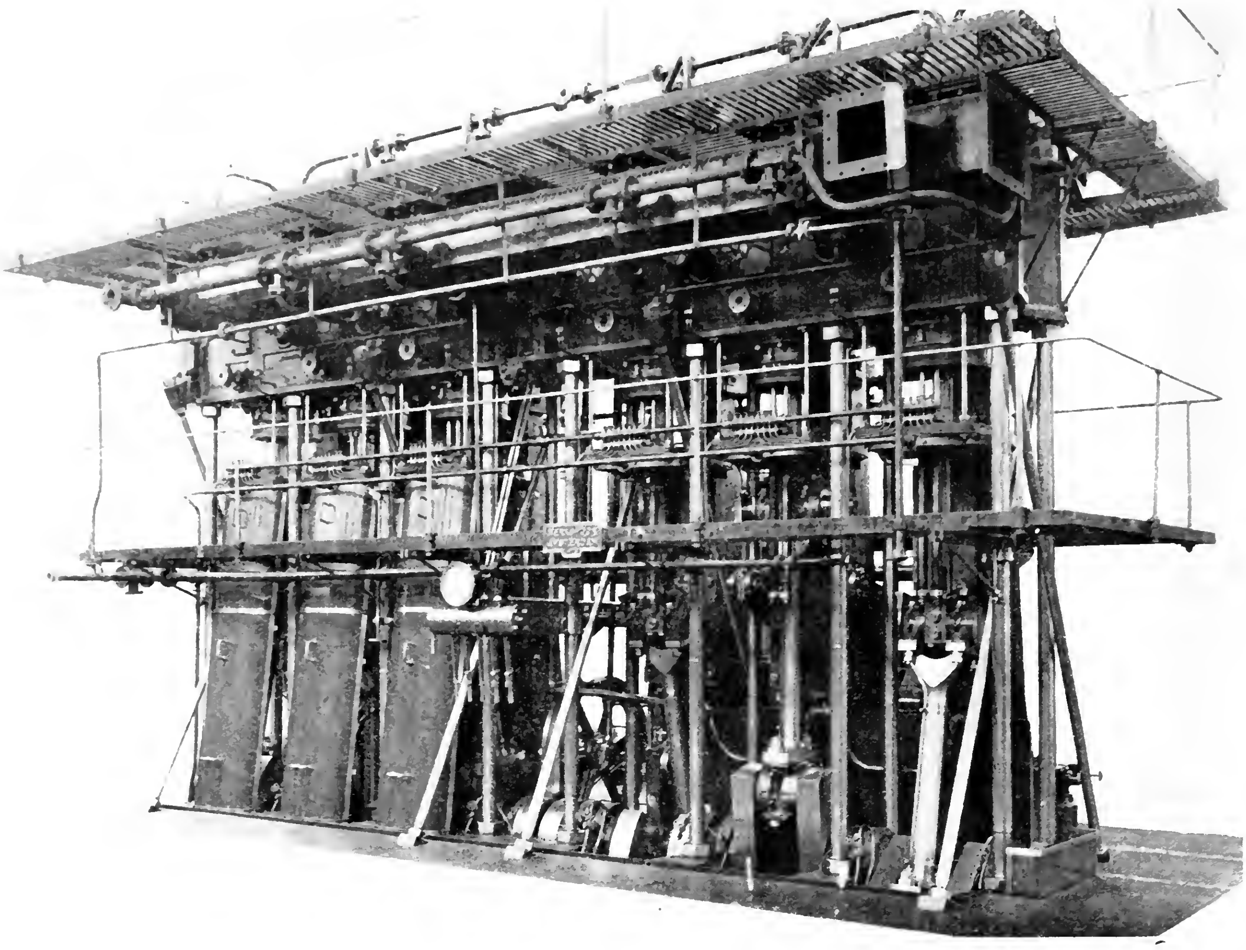

Fig. 6 Four-Cycle-Type Reversible Marine Diesel Engine (1020 b.hp., 1360 i.hp. at 120 r.p.m.). Weight 122 Tons. Fuel Consumption Under 4½ Tons per 24-Hour Day

Because of the strain thrown on the machinery by reversing the direction of a large ship, the tackling of the reversible propeller is by no means a simple matter; but every part, being massive, has proved more than capable of handling the power, without showing noticeable wear. The fact that the owners of the *Poseidon* ordered other similar ships after it had been in service for some time, is evidence that the reversible propeller is satisfactory in practice.

Since this paper was written I have received cabled permission to give drawings and details of our new submarine engine. The motor shows a remarkable advance in design and construction and is perhaps the most simple Diesel engine ever built. On the test bed at Amsterdam there is now a six-cylinder set designed to operate at 400 to 450 r.p.m. on the four-cycle principle. It can develop 500 b.hp. when running at 400 r.p.m., and is capable of a considerable overload. It only weighs about 12 tons without flywheel, which, I believe, is lighter than any existing two-cycle Diesel submarine engine of similar power. An entire cylinder may be removed and another substituted in about two hours, while a piston can be taken out and inspected in about 15 min. It has very few cast parts, the only castings of note being the cylinder boxes, the cylinders, the pistons and the air-compressor cylinders. Instead of cylinders of the ordinary type there is a long cast iron box running the length of the engine into which the cylinders are placed from below and held in position by a flange, the cylinder and cylinder head being in one, which gives a very large water-cooling space over and around the combustion chamber. This cylinder box is connected to the bedplate by steel rods 3 in. in diameter, thus taking all strains from the bedplate, and consequently each bearing is suspended directly from the cylinder, which enables the bedplate to be made from light cast-steel bearing blocks connected by cast-steel girder beams along the engine, thus dispensing entirely with cast-steel, iron or bronze bedplate. To collect the oil from the working parts, the bottom of the engine is enclosed by a steel plate 1⅛ in. thick. The running gear is entirely enclosed by steel plates which are easily detachable. Each working

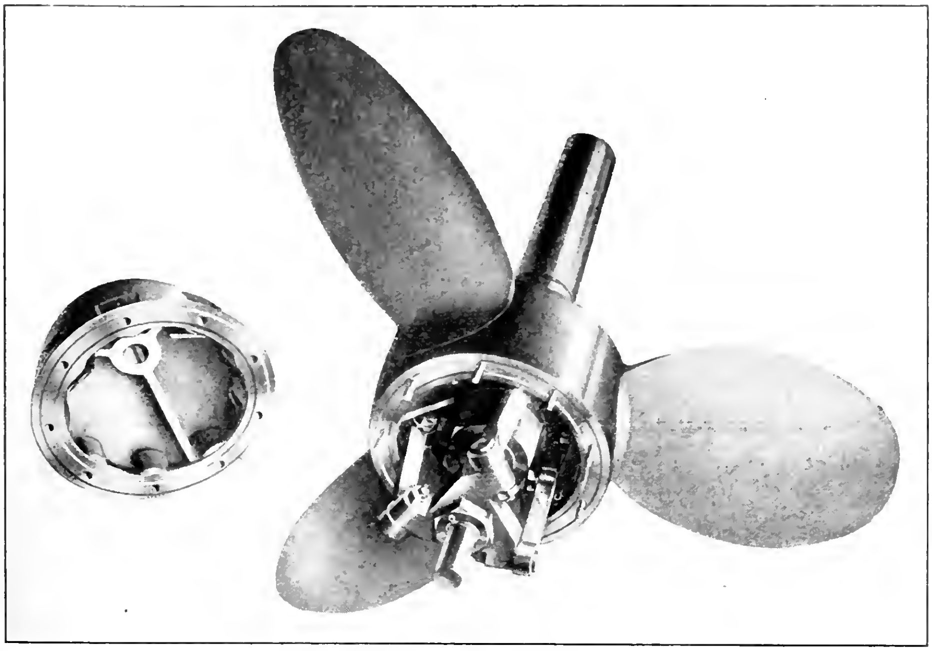

Fig. 7 Reversing-Blade Propeller

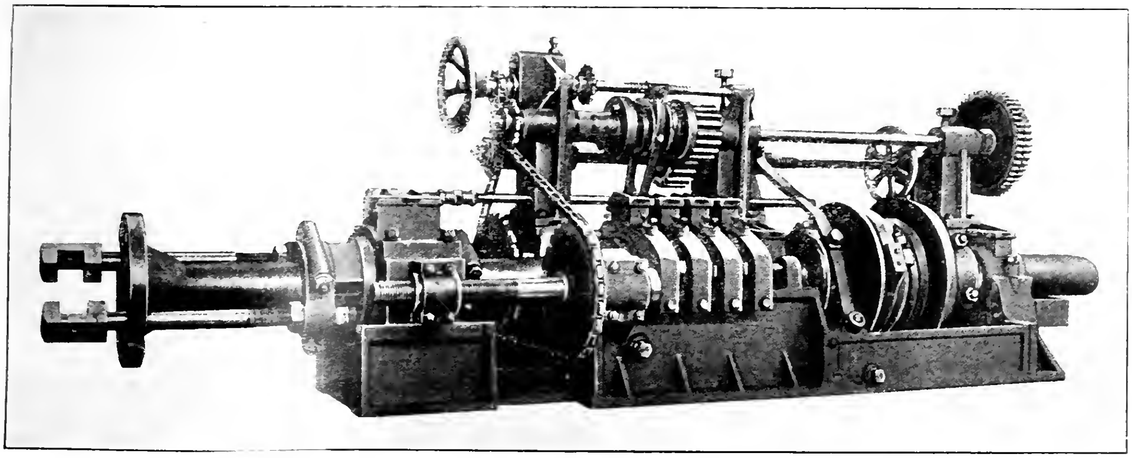

Fig. 8 Mechanism and Thrust Block for Operating Reversing-Blade Propeller

cylinder is made in two parts, the upper part being cast in one piece with the cylinder head, while the lower part is detachable and enables the pistons to be removed very quickly. This extension also is water cooled, a sheet metal band being placed entirely around it. An innovation is to be seen in the blade steel springs for closing the valves, which give less vibration and take less height: and only three springs are required for two cylinders. It is not necessary to water-cool the pistons with this size of engine; but some sort of cooling device is advisable, so the air aspired by the down stroke of the main piston is drawn by suction through the cylinder box from the upper part of the crank case and is replaced by cool air blowing through the bent pipes. In order to overcome the valve difficulty sometimes experienced with air compressors, we designed a special valveless three-stage compressor, and this is situated at the forward end of the engine. The three stages are driven by three cranks having angles of 120 deg. to each other. Each cylinder has inlet ports at the bottom, and the low-pressure and middle-pressure cylinders have an outlet hole at the end, while the high-pressure cylinder has an outlet valve at the top where it can easily be taken out if necessary. Thus there is only one valve in the entire compressor.

My personal opinion is that in six or seven years every new cargo ship of under 10,000 tons displacement will be equipped with internal-combustion engines of the crude-oil type, except in a few rare instances where special circumstances of service will cause steam engines to be the only suitable machinery. The advantage of the Diesel-type engine will be appreciated most during normal times. When low freight rates return, it will not be possible for steamers to compete with motorships on many routes, particularly where long distances have to be covered, and especially where tramps are concerned. In hard times shipowners will be forced to use the most economical propulsion. Other methods of steam power cannot be made as efficient and as economical as the crude-oil engine, unless the price of oil should rise to phenomenal figures.

DISCUSSION

A. J. Wood said that with regard to the author's remark that one particular type of four-cycle Diesel engine was lighter per horsepower than the same capacity unit of a two-cycle, he would like to ask whether there was any particular design followed to effect the result, and whether there were other types of engines that had effected the same results. Mr. Lisle replied that in marine work the four-cycle engine was lighter, owing to the additional parts necessary for the two-cycle, particularly the scavenging pumps. Theoretically the two-cycle should be much lighter, but on those put to service the two-cycle engines had been heavier than the four-cycle. That included the compressor of the engine. There were no scavenger pumps with the four-cycle engine, and that saved an immense amount of weight.

Julius Kuttner, with reference to reversible propellers, asked about the fact that the blades on solid propellers frequently broke, and separate solid blades were always carried on the deck of the ship. If the solid one broke off, were not the chances of breaking in the reversible propeller much greater? Mr. Lisle replied that he did not see why it should be so. They might break off if they hit anything, of course, but they could be replaced just as easily, and it was possible to make them just as strong, this being a question of design more than anything else.

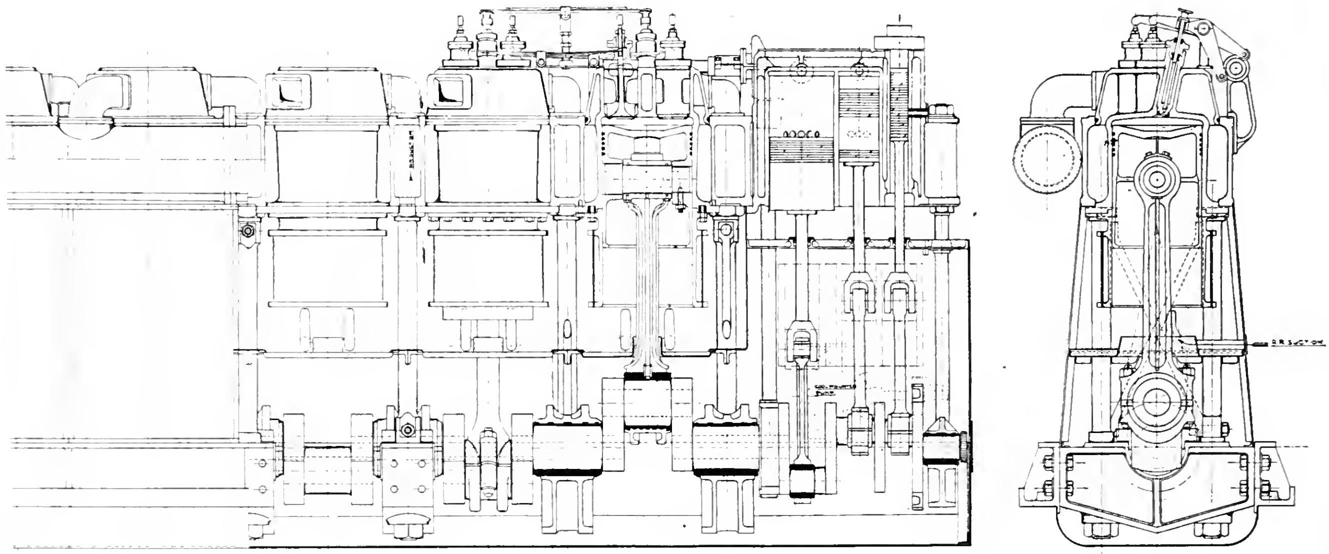

Fig. 9 Submarine Diesel-Type Engine. There is also a Design of Smaller Power in Which the Weight Has Been Reduced to 31.5 lb. per b.hp.

THE DOWNFLOW TYPE OF STEAM BOILER

By JOHN CLINTON PARKER, PHILADELPHIA, PA

Member of the Society

THE downflow principle is shown diagrammatically in Fig. 1. The reservoir has separate compartments for water and for steam, with a swinging valve between, which automatically forces water into the tubes to replace that which is discharged by each drop in pressure. The straight water tubes are arranged in the form of flattened-coil elements leading downward from the water compartment with direct connections from the bottom ends to the steam compartment. A check-valve at the water-inlet end of each element prevents reversal of the flow.

The water is maintained at a given level in the lower compartment of the reservoir through a feed connection in the regular way. It flows downward by gravity into the elements and seeks the same level in the upcast. When heat is applied, the water in the upcast is soon discharged into the reservoir by the expansion of the steam formed in the lower tubes. The water then runs down from the reservoir to regain its level in the upcast. This is frustrated by continuous evaporation, mainly in the lower tubes. The more the fire is forced, the greater is the proportion of steam in the upcasts, the larger is the unbalanced head of water, and the more rapid is the flow through the tubes.

A 20-hp. downflow boiler enclosed in a steel casing was built in 1899 at Roach's shipyard in Chester, Pa. There were three drums 10 in. outside diameter, 3 ft. long, 160 tubes 1 ft. outside diameter by 3 ft. long, and 36 firebox tubes $1\frac{1}{2}$ and $1\frac{3}{4}$ in. The headers consisted of a pair of cored tube sheets with cored cover plates which when bolted to the tube sheets formed return bends, the idea being that the one large outside joint would obviate a lot of inside ones, a steam-tight joint not being essential between the inside ribs. Experience with this boiler, however, led to the development of the two-tube junction box and the use of larger tubes.

STANDARD DOWNFLOW BOILER

Fig. 2 shows a standard design. The drums are constructed in accordance with the best practice, using high-class material and workmanship. The longitudinal seams are butt-strapped and triple-riveted, giving very high efficiency.

The diaphragm of $\frac{1}{4}$-in. steel plate is riveted to the shell and arranged to form a pocket at the front to collect the scale discharged from the tubes. The anti-priming valve is hinged to the diaphragm head and serves as a manhole for the lower chamber. The bottom of the drum below the level of the nipples leading to the elements forms the sediment pan or mud drum. An inverted angle with closed ends is placed over the blow-off opening, making the blow-off effective over considerable area.

The elements are formed by expanding the tubes into the junction boxes which hold two tube ends, with a handhole opening opposite each.

The tubes in the upper pass form the feed element or economizer, which in this unit is 16 tubes wide and three tubes high. The top end is connected to the drum with an expanded nipple, and the feed connection is in the junction box at the front end of the first tube in the element. At the rear end of the tube is placed a non-return valve, which prevents the feed going the wrong way and entering the drum through the inlet connection.

The flow in the economizer element is forward and back alternately through each tube in the top row, then down to the next row, and so on, finally discharging through a vertical upcast into the rear drumhead above the diaphragm. When the feed is shut off, the drum connection furnishes the economizer element with a circulation.

The lower or evaporating elements are two tubes wide, passing the water twice across the furnace at each level. The connection from the drum to the upper or induction end is made by an expanded tube entering an "inlet" box which supplies two elements. Each element has a non-return valve, located

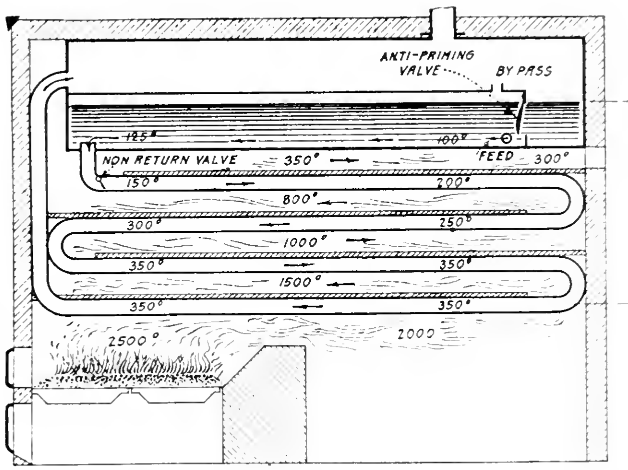

Fig. 1 Evaporation Diagram Illustrating Downflow Principle

in the inlet box. The valve fits into the tube end and is held in place by a loose pin, which forms a positive stop when the handhole is closed. The valve is loosely hinged with plenty of clearance, and is easily removed through the handhole for cleaning. The lower end of each element is connected to the steam chamber by an independent upcast. The arrangement of the tubes permits the free and independent expansion of every tube without strain on any joint.

The large swinging valve at one end of the water compartment closes as often as steam is withdrawn through the steam opening with sufficient rapidity to lower the pressure. In practical service, pressure changes are more or less frequent, sudden and pronounced, according to the irregularity of the service and the severity of the demands for steam. In such service as supplying steam hammers, rolling-mill engines, electric-power plants, subject to sudden heavy peak loads, or warships which may require full speed on a moment's notice, the steam pressure may be suddenly lowered 10 or 15 lb., or even more, in a very short space of time. In every such case a quantity of water, proportionate to the drop in pressure and the speed with which it takes place, is discharged from

Abstract of paper presented at the Annual Meeting of the American Society of Mechanical Engineers, December 1916. Pamphlet copies of complete paper may be obtained. Price 10 cents to members; 20 cents to non-members.

tubes of any type of water-tube boiler by the sudden evaporation due to the lowering of the boiling point along with the pressure.

Under conditions of a drop in pressure causing displacement of water from the tubes, a bypass controlled by a float-operated double-beat valve equalizes the pressure.

The double valve just referred to may be seen in Fig. 2 over the swinging valve. It is balanced and operates without touching the sides of the bypass openings through which the disks move. Sufficient clearance is provided as a vent to allow the water compartment to fill to the water level under normal conditions. When a pressure drop occurs with sufficient suddenness to affect the circulation, the anti-priming valve closes. The excess pressure forces water into the tubes until the float opens the bypass. This releases the pressure and allows the

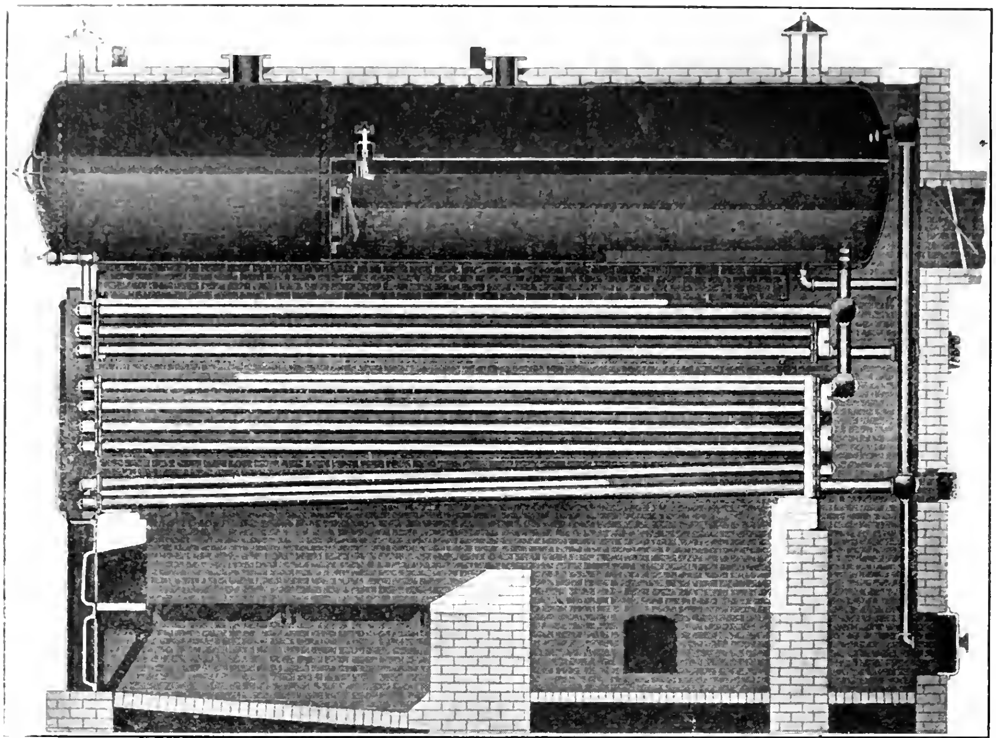

FIG. 2 SINGLE-ENDED DOWNFLOW BOILER, STANDARD DESIGN

water compartment to fill, and the operation is repeated intermittently as long as the pressure continues to fall. The prompt replacement of the desirable quantity of water in the tubes after each pressure drop can be provided for in the design by proportioning the water compartment to hold between the upper and lower levels at which the anti-priming valve closes and opens, the quantity of water required to meet the severest conditions.

Following are some of the new ideas embodied in the latest cross-drum design of downflow boiler.

a The diaphragm is omitted. The front drum serves as the water compartment. The steam drum drains into the water drum through a three-tube connection controlled by the anti-priming valve. One 4-in. tube connection serves as a bypass. The cross drums are more convenient for inlet and upcast connections. The drums are free from unequal strains, and are more accessible.

b The feedwater-heating coiled element is swung so that it can be moved 2 in. sidewise at either end when necessary to remove and replace a junction box, or when access to the handholes, entirely clear of the inlet or upcast tubes, is desired for cleaning or replacing tubes. It is not necessary to move the tubes to insert a tube cutter, expander or cleaner, but it may sometimes add to the convenience.

c The bottom row of tubes go through a crossbar at the rear end which supports the tubes above it. The whole bottom row can be moved 2 in. sidewise to bring the upcasts entirely clear of the junction boxes or handholes when desired. The bar is carried on ¼-in. rollers. It is made in box shape to form an air trap to prevent leakage of hot gases from the combustion chamber into the rear casing. This box has small holes to admit sufficient air to direct any leakage *into* the combustion chamber in place of the reverse direction. This keeps the bar and rear casing cool and prevents gradual deterioration from excessive heat. The movable box joints and openings where the tubes pass through are made fairly tight so that the leakage is small. What does get through aids combustion.

d In the new downflow design, the entire bottom row of tubes operates on the inclined-tube principle. The flow through the two bottom tubes of each element is now parallel in place of serial. These two tubes now discharge directly into one 4-in. upcast like the two staggered bottom tubes of a Babcock & Wilcox section. None of the other tubes above the bottom row discharge into this upcast. The steam is discharged above the water level. It does not have to pass through water and is entirely free to escape into the steam compartment without interference under all conditions of operation.

ANNUAL MEETING DISCUSSIONS

Written Discussions of the Papers Presented at the Thirty-Seventh Annual Meeting of The American Society of Mechanical Engineers, New York, December 5 to 8, 1916

BELOW are the remaining written discussions of the papers presented at the Thirty-Seventh Annual Meeting of The American Society of Mechanical Engineers, held in New York City, December 5 to 8, 1916. One half of these discussions were published in the last issue of The Journal, supplementing the full account of the meeting which appeared in the January issue.

The discussions are printed substantially in full, and will be found to contain a large amount of valuable material supplementing the subject-matter of the papers. Following the discussions are given the authors' closures, which refer also to the oral discussion abstracted in the January number.

WATER FOR STEAM BOILERS—ITS SIGNIFICANCE AND TREATMENT, ARTHUR C. SCOTT AND J. R. BAILEY

M. F. Newman. The authors seem to be unaware of the fact that the most highly efficient water purification is carried on without dependence upon heat. The main factors in boiler-water purification are not heat, soda ash and blowing off, with possible filtration, but accurate softening and purification carried out independently of the variables encountered in the irregular flow of water through the heater and the uncertain degree of precipitation within the heater.

The causes assigned for corrosion include the presence of sodium chloride (evidently the authors have confused magnesium chloride with sodium chloride, since it is a well-known fact that sodium chloride within the boiler is a neutral salt). If sodium chloride were an active corroding substance, then the majority of the boilers in operation in this country would be constantly showing evidence of corrosion.

The authors assign as cause of foaming and priming a concentration of alkali salts, giving secondary place to silt, organic matter, loosened scale, lubricating oil, etc. This belief is commonly held, but it has been found that in the absence of substances in solution which form precipitates upon concentration, water containing alkali salts can be concentrated to a very great degree without any appreciable effect on the steaming quality of the water. The foaming is not due primarily to the alkali salts but to the accumulation of lime, magnesia, iron, etc., that are forced out of solution, thus befouling the water in the boilers with suspended matter, which, by ebullition, is carried to the surface of the water, interfering with the liberation of steam.

The authors' classification of water containing less than 8 grains per U. S. gallon of scale-forming matter as very good, water of from 8 to 15 grains as good, and water with 15 to 20 grains as fair, is altogether fallacious, because no distinction is drawn between temporary hardness and permanent hardness. In any water supply where permanent hardness is present all of the hardening substances become scale-forming substances due to the cementing action of the salts of permanent hardness. Under present-day practice of boiler operation, where the rate of evaporation is carried as high as 300 per cent of rating, any water containing permanent hardness rapidly concentrates to the point where scale formation results, and under such high evaporation any scale formation is quickly followed by tube failure.

The authors' statement that all water softening consists of lime alone, or lime and soda ash, and that no chemicals other than lime and soda ash are ever used under conditions of water softening, is erroneous, there being few water supplies where the precipitation of lime and magnesia can be carried to the proper minimum with these two reagents alone. The adherence to theoretical calculations of the laboratory for requirements of lime and soda ash to precipitate hardening substances is responsible for many failures to obtain from water treatment the results anticipated. There are more factors than the calcium and magnesium salts to be taken into consideration, and each water supply presents a separate problem in itself.

The authors' statement that, after a water-softening plant is in proper working order, the adjustment of chemical feed to raw water, as a rule, will not necessitate any considerable change in the amount of lime and soda ash to be used, can scarcely be reconciled with the facts, when it is known that many of the river-water supplies pass through a seasonal range of from 500 to 700 per cent variation. It is scarcely to be expected that such variations could be met with "a practically constant feed of reagents."

It is quite true that it is not necessary nor desirable to remove all of the calcium from boiler feedwater, but the result obtained in reducing the hardness with different water supplies should and must be brought to a definite standard so that the softened and purified water will contain approximately the same amount of lime and magnesia under all conditions, regardless of the varying quantities of sodium salts or other impurities. The reduction of hardness to entirely eliminate permanent hardness and keep the remaining lime and magnesia compounds within a total of two grains per gallon, is the result obtained in correctly softening a water supply from any source. This degree of softening must be constantly maintained, and on such uniform softness depends the success of water purification for boiler feed.

The statement that large amounts of sodium chloride tend to make water corrosive is erroneous. It is the various substances in solution, notably magnesium chloride, which, under boiler conditions, produce the corrosive effects. Waters containing large amounts of alkali salts, especially sodium carbonate and sodium chloride, have a tendency to foam, not because of the presence of these salts alone, but because with these salts present, much lime or magnesia is precipitated, due to concentration and heat, and the suspended matter thus formed produces a foaming tendency.

The foaming resulting from the use of soda ash is mostly due to forcing calcium and magnesium out of solution, or to the soap-producing effect from grease and oil.

The relative terms *high* and *low* as applied to alkali salts do not determine the suitability of water for softening and purifying for boiler feed, for with the reduction of calcium and magnesium to a minimum and with an elimination of oil and grease, waters containing as high as 200 grains per gallon of sodium salts are frequently used for boiler feed without any difficulty being experienced with foaming and priming, and when using such water the controlling factor is to avoid too

great concentration of the residual calcium and magnesium salts.

The dependence placed upon the empirical soap test for determining hardness, and the reliance on lime and soda ash, or upon heat and soda ash alone, give a false impression of the true procedure required to soften and purify boiler feedwater from any source. Neither heat and soda ash alone, nor lime and soda ash treatment alone, will meet all conditions so generally as to permit of the statement that such procedure includes all of the requisites for purifying boiler feedwater.

F. F. VATER. I would like to ask why the hot process of water softening is classed in the paper with such devices as live steam purifiers and boiler compounds. The cold process would be more appropriately classified with these than the hot process.

Any chemical reaction will be more thorough and quicker with heat applied than without. This being true, the treatment of water hot offers possibilities of efficiency not attainable in a cold process. Treating water at 200 deg. fahr. will enable one to begin with a water containing 25.59 grains of incrusting matter per gallon and deliver it into boilers with a hardness of 2 grains per gallon with a causticity of from 0.4 to 0.5 of a grain per gallon and an alkalinity of 3½ to 4 grains per gallon, not occasionally, but constantly.

Again, treating water at 200 deg. fahr. will enable one to begin with a water containing 17.97 grains of incrusting matter per gallon and deliver it into boilers having zero hardness as determined by soap solution, causticity 1.8 and alkalinity 6.7 grains per gallon.

A gravimetric analysis of the treated water shows but 85/100 of a grain of incrusting matter per gallon.

I would suggest that the authors compare labor cost of operating a cold process, either intermittent or continuous, with the records made by the hot process, which is $35.00 per month for a plant handling 80,000 gallons of water an hour, operating 24 hours a day. Plants of this size are in continual operation, and there is no reason why one cannot be built to handle any quantity of water.

There are advantages in plant operation obtained by treating water hot other than chemical and labor costs, but space will not permit bringing these out here. Only one plausible criticism of the hot process is in existence, and that is the possibility of heat losses. Hot-process machines can, however, be placed in open air, 10 deg. below zero, and covered, so that the loss in temperature between the heated water and the water as it comes from the machine will not exceed 0.5 deg. fahr.

GEO. H. GIBSON, whose discussion of this paper was publsihed in full last month, appended to this discussion the description of an apparatus by means of which the softening reagents used in hot-process systems are fed with great accuracy and sensitiveness. The description follows:

This flow proportioner is of the type in which the secondary flow, the chemical reagent in this case, is discharged through an orifice under a pressure proportional to the velocity head of the raw water entering the softener. Referring to Fig. 1, *A* is a perforated diaphragm inserted in the raw-water supply pipe. From each side of the diaphragm small pipes lead to the sides of the differential piston in cylinder *B*. The piston rod extends through both ends of the cylinder, to avoid unbalanced areas, and its lower end carries a flat valve disk covering an opening through which chemical solution is pumped constantly by the circulating pump *C*. The differential pressure forces the valve disk against the escaping fluid, and a pressure is therefore maintained upon the latter proportional to the differential head due to the flow of raw water past the orifice at *A*. The bulk of the chemical escapes under the edges of the valve and returns to the chemical tank, but a portion discharges through a small orifice into the open funnel *D*. Due to the proportionality of pressures this flow is at all times proportional to the flow through the raw-water orifice. The chemical-proportioning orifice, not being in contact with the atmosphere, does not accumulate scale or sediment. From the funnel the measured portion of the chemical descends to the chemical feed pump *E*, by which it is lifted to the top of the sedimentation tank, there encountering the heated raw water from the open feedwater heater.

It is found that in actual practice the accuracy of feeding of reagent is within 2 per cent: in fact, a pressure gage com-

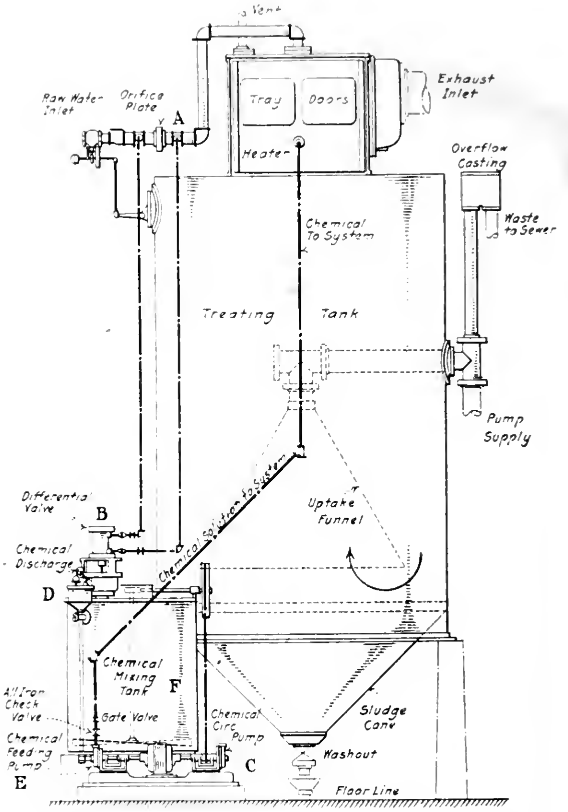

FIG. 1 CHEMICAL-FEEDING APPARATUS FOR USE WITH HOT-PROCESS WATER SOFTENERS

municating with the solution pressure chamber makes a very good flow meter for the raw water, and the total amount of raw water used can also be determined from the amount of chemical removed from the chemical tank.

The main supply of the chemical reagent is kept in constant agitation in the tank *F* by paddles driven by the same motor which operates the two pumps. This tank is located on the ground, avoiding the lifting or hoisting of chemicals, and the whole chemical feed apparatus is in the open and readily inspected. The positive feed of the reagent renders the action of the apparatus entirely independent of any back pressure carried in the softener.

The combined softener and feedwater heater, because of its small size, due to the more rapid reaction and sedimentation,

can ordinarily be placed within the boiler room, without requiring special housing or foundations. There is also usually a considerable saving in piping and other installation costs.

CLOSURE BY MR. BAILEY

J. R. Bailey. Mr. Fowler deplores the skipping over, in the paper, of "the ingredient which occurs in almost all boiler waters—organic matter," but the following extracts from the paper indicate that this criticism is not justified: "Waters low in mineral content but high in organic matter, though perfectly clear, may be troublesome, because a part of the organic matter precipitates. Peaty waters are harmful to boilers by reason of the vegetable acids they contain. The bad effect of mineral or vegetable oils finding their way into the boiler-feed water is well understood."

Mr. Newman takes exception to our belief that "large amounts of sodium chloride also tend to make waters corrosive," overlooking the fact that, where the hypothetical combinations in a water analysis show magnesium chloride, all the sodium is reported as chloride. Under such conditions it would be expected that a heavy concentration of chlorine ions, reported in the main as sodium chloride, would necessarily increase the corrosive action. He further objects to the classification of a water as *good* that contains less than 8 gr. per gal. of scaling salts, because "no distinction is drawn between temporary and permanent hardness:" on the contrary, this distinction is emphasized in the paper with utmost clearness.

Mr. Newman also points out that "the adherence to the theoretical calculations of the laboratory for requirements of lime and soda ash to precipitate the hardening substances is responsible for many failures to obtain from water treatment the results anticipated." My thorough accord with this contention is attested by the statement in the paper that "the best results can be obtained in water softening by controlling with chemical tests the successive batches of water treated." Mr. Newman's statement that there are "few water supplies where the precipitation of lime and magnesia can be carried to the proper minimum with lime and soda ash alone," is challenged by the satisfactory results the process has given in the hands of thousands of operators.

I wish especially to take exception to the comment by Mr. Newman that "the authors' statement that after a water-softening plant is in proper working order the adjustment of chemical feed to raw water, as a rule, will not necessitate any considerable change in the amount of lime and soda ash to be used, can scarcely be reconciled with the facts, when it is known that many of the river waters pass through a seasonal range of from 500 to 700 per cent variation. It is scarcely to be expected that such variations could be met with a practically constant feed of reagents." It is to be observed that we say that *as a rule* no *considerable* change in the chemical feed will be necessary. Why did Mr. Newman not quote this statement in the paper: "It is impossible to regulate automatically the feed of chemicals to compensate fluctuations in the scaling ingredients of water"? If there is any one point that is stressed in the paper, it is that without chemical control the lime-soda-ash process will probably prove unsatisfactory. Mr. Newman asserts that a concentration of alkali salts cannot be assigned as a cause of foaming, but that foaming is brought about by the accumulation of lime, magnesia, iron, etc. The question arises why, if this be the case, certain waters in alkali countries cannot be used in boilers? It is a very common observation in laboratory practice that solutions, after attaining a certain viscosity through concentration of salts of any nature, bump and foam, and such a condition is certainly analogous to that which may arise in a boiler, where the water used is high in alkali content.

Mr. Kent minimizes the waste heat that is due to boiler scale, but I think the coal bills of many steam users will offer mute protest to his contentions.

What Mr. Applebaum says about the Permutit process demands attention, but the fact remains that Permutit softeners have not yet been generally introduced in this section of the United States.

Mr. Vater and Mr. Gibson contribute some very interesting data on the very satisfactory results obtained in the hot-process softeners, of the efficiency of which there is no question. The fact should not be lost sight of that a great many operators of small steam plants cannot afford the investment required for the installation of a patented water softener. Their only hope lies in a home-made water softener, and in using the cold process of treatment with lime and soda ash. All large steam users should install a standard softener with mechanical features that will demand a minimum of supervision and yield maximum efficiency.

THE IMPACT TUBE, SANFORD A. MOSS

Victor R. Gage. Work done on blower testing in the Sibley College laboratories verifies some of the conclusions drawn by Mr. Moss. We have found that the impact tube gave reliable and consistent results, not subject to error from slight misalignment or from stream lines not parallel to the pipe walls. Difficulty has been encountered in obtaining a satisfactory method for determining the pressure head, i.e., the so-called "static pressure" of moving fluids.

It is our custom to use as small an opening as is possible, without rounding the corners, but with all burrs removed, and with the pipe carefully smoothed, for measuring pressure head. Our laboratory experience has led us to this. In one case, using a large hole, the pressure head was of a considerably different value than when the manometer was connected to another and exactly similar hole about nine inches away. By greatly reducing the size of the holes, the values became practically the same. Further investigations indicated the existence of eddies and standing waves. The conclusion was drawn that a large opening was subject to more danger of receiving some (positive or negative) impact from currents of fluid not parallel to the pipe wall, and that the skin-friction effect would protect a small hole to some extent. The smaller the hole the more the protection. This conclusion is tentative. With ordinary or higher velocities the flow is always turbulent, and care must be exercised in obtaining measurements of pressure head, both as to the means used and the place where the instruments are located.

With air at very high velocities (about a mile a minute) it was once found that the pressure head was not constant across an 8-in. pipe, and was actually less than atmospheric pressure although the blower was discharging into atmosphere through the pipe. The discharging steam was convergent after leaving the pipe.

For several years the arrangement shown in Fig. 8 of Mr. Moss' paper has been used in place of a pitot tube, as being more satisfactory, in the regular students' laboratory experiment upon testing of blowers.

In regard to the use of a thermometer, we have used one first bare and then protected, placed in the jet of steam in a throttling calorimeter to illustrate the direction of the changes in the adiabatic conversion of heat into kinetic energy, and

back again to heat. The bare thermometer bulb only partially checks kinetic energy, there is a very perceptible temperature rise upon furnishing a more complete checking of the velocity, although the bare bulb indication is considerably higher than the temperature corresponding to isentropic expansion.

JOHN L. ALDEN. An impact tube with properly made static pressure holes in the pipe wall will give as accurate a determination of velocity as the best pitot tube. In addition, the tube itself is much less delicate and is more easily manipulated because of the absence of the tiny static-pressure orifices. However, it is extremely doubtful whether the large static openings in the pipe, as described by Mr. Moss, are not a source of error. Holes ¼ in. to 1 in. in diameter are very likely to be influenced by the velocity, and will probably give a combined reading of static and velocity pressure. If anything, the error is greater by using a large hole and getting velocity influence than by using a small hole and having a slight possibility of leakage. This leakage trouble is one not ordinarily encountered, I think, and it would seem that a lower static reading should be attributed to the measurement of the true pressure with the small hole rather than to leakage. The tests by W. C. Rowse at the University of Wisconsin, recorded in Vol. 35 of the Transactions, show pretty conclusively the effect of large static holes in recording velocities lower than the actual. The same conclusions apply in a considerable degree to static orifices in a pipe wall. The piezometer ring is unreliable, for the reason Mr. Moss has given. It does not correctly average the static pressures around the pipe.

The impact-tube law as stated in the paper is merely a restatement of the law of conservation of energy. In other words, the kinetic energy of the jet may be transformed into potential energy in the impact tube with only the immeasurable loss in the tube itself. Such a conclusion should be expected, as the impact tube is primarily an instrument measuring energy.

Testing a fan by the use of a single impact tube in the discharge pipe, as shown in Fig. 10, does not give a true indication of the output of the fan. Two tubes must be used, or the static vacuum at the inlet must be measured, for otherwise the fan is not credited with the negative pressure which it is producing. This suction is used in creating flow through the inlet. Part of it is shown in the form of velocity and the rest is lost in overcoming the resistance of the inlet. Where the inlet and outlet areas are equal, the pressure not credited to the fan is the entry loss referred to. The method shown in Fig. 11 is the correct one for fans and blowers as well as centrifugal pumps.

The writer believes that the orifices shown in Fig. 18 would give very doubtful results if the velocity of approach were appreciable. From the standpoint of smooth stream flow these nozzles are very bad. At high entrance velocities, 3000 feet per minute or greater, the contraction of the jet at the throat would probably be great enough to prevent filling of the mouth of the orifice. In other words, the condition of Fig. 12 would be greatly increased, and the expansion of the jet to the size of the orifice would not take place until the end of the orifice was passed. If this condition actually occurred, the area of the orifice could not be used in calculating the volume. Unless each orifice were calibrated for all high velocities, it would seem unsafe to use this form. If the approach were more gradual and the fillets were large to smooth out the stream lines, an orifice might be made which would cause no contraction whatever.

CLOSURE BY MR. MOSS

SANFORD A. MOSS. Mr. Alden refers to Mr. Rowse's paper in Vol. 35, Trans.Am.Soc.M.E., as showing that large static holes give error in static pressure. In all cases the errors reported by Mr. Rowse in measurement of static pressure were in the static pressure in a pitot tube. The reason they were in error is due to the fact that the flow was not parallel to the surface. Mr. Gage also notes error due to large static holes when there were eddies. I believe, that with proper length of straight pipe, or other arrangement for insuring that flow along the surface is parallel to it, the size of the static hole is unimportant. However, there is no objection to a small hole if any one prefers it and has tight piping.

Mr. Alden has some fears regarding the shape of the orifices illustrated, but actual experience with these orifices for many years shows that Mr. Alden's fears are groundless and that the mouth is filled in all cases, even for extremely high velocities. The essential point of an orifice is a large fillet or gradual curve just preceding a parallel portion. A long gradual approach is not necessary. In steam-turbine nozzles, where very high velocities are used, this has also been found to be the case.

The errors in the theoretical adiabatic perfect-gas formula to which Mr. Buckingham alludes are negligible for all engineering work. The validity of the use of the theoretical formulae has been justified by a great deal of experimental work.

In The Journal and pamphlet editions of the paper, owing to an error, the term *down stream* was used instead of *up stream* in a number of cases.

THE PROPORTIONING OF SURFACE CONDENSERS, GEORGE A. ORROK

WILLIAM D. ENNIS. In their present forms, Mr. Orrok's several papers would all of them need to be consulted to obtain a definite program for procedure in condenser design. The following is offered as a summary and amplification of his method.

Let W = maximum weight of steam to be condensed, lb. per hr.

t_s = temperature of steam

Q = weight of condensing water, lb. per hr.

t_0 = inlet temperature of condensing water

t_1 = outlet temperature of condensing water

S = aggregate external surface of condenser tubes, sq. ft.

U = coefficient of transmission

t_m = mean temperature difference

L = latent heat of vaporization of steam at temperature, t_s

x = dryness of the steam at temperature t_s.

Then

$$WxL = Q\ (t_1 - t_0) = SUt_m \ldots\ldots\ldots\ldots [1]$$

The following rules will fix values to be taken in the above:

If H' denotes the B.t.u. in 1 lb. of steam at throttle conditions, h_s the heat of liquid corresponding with the temperature t_s, and B the steam rate of the engine, lb. per i.hp-hr., then

$$xL = H' - h_s - \frac{2545}{B} \ldots\ldots\ldots\ldots [2]$$

This rule is on the safe side, since it assumes all heat not converted into work to be still present in the exhaust.

For t_1 use a value 5 deg. to 10 deg. below that of t_s.

The steam temperature t_s is that corresponding with the absolute steam pressure p_s at the exhaust nozzle. If v denotes the vacuum at the condenser, in. of mercury, and v_n the loss of vacuum between condenser and exhaust nozzle (also in. of mercury), then, ignoring the influence of any air present,

$$p_s = 14.696 - 0.493\ (v - v_n) \ldots\ldots\ldots [3]$$

For good design, Orrok uses $v_n = 0.2$.

The value of U that is now recommended by Mr. Orrok is $325\ V^{0.6}/t_m^{\frac{1}{8}}$, where V = water velocity in tubes, ft. per sec., which water velocity varies from 7 to 10. In usual practice, this is equivalent to a value of U around 800, or about four times the value once employed. The expression given for U is sufficiently applicable for any standard material in a new tube. (Foul tubes may decrease U 50 per cent.) The effect of the steam-richness ratio is now thought to be represented by $(p_s/p_t)^2$ rather than by $(p_s/p_t)^5$ as in Vol. 32, Page 1162. With tight condensers and good vacuum pumps, (p_s/p_t) may be expected, according to Mr. Orrok, to lie between 0.95 and 0.97. The constant in the expression for the value of U has been made to contemplate such values. Safe values of U for commercial design are further considered below.

The mean temperature difference, assuming that the exponential law holds (see Trans. Am.Soc.M.E., Vol. 32, Page 1211), is

$$t_m = \left[\frac{\frac{1}{8}\ (t_1 - t_0)}{(t_s - t_0)^{1/8} - (t_s - t_1)^{1/8}}\right]^{8/7} \ldots\ldots\ldots [4]$$

The arithmetical mean is $t_s - \dfrac{t_1 + t_0}{2}$. The logarithmic mean is

$$\frac{t_1 - t_0}{\log_e \dfrac{t_s - t_0}{t_s - t_1}} \ldots\ldots\ldots [4a]$$

(See Trans. Am.Soc.M.E., Vol. 32, Page 1211.) This gives a value close to t_m.

The expanded equation for design is then

$$Q\ (t_1 - t_0) = \frac{325\ V^{0.6} S}{t_m^{1/8}} \cdot t_m = 325\ V^{0.6} S\ t_m^{7/8}$$

$$\text{or, } S = \frac{Q}{40.63\ V^{0.6}} \left\{ (t_s - t_0)^{1/8} - (t_s - t_1)^{1/8} \right\} \ldots\ldots\ldots [5]$$

Let d = outside diameter of tubes, in.
t = thickness of tubes, in.
n = number of tubes in each pass of condenser
l = aggregate length of passes, ft.

Then area per tube for passage of water $= \dfrac{0.7854\ (d - 2t)^2}{144}$ $= 0.00547\ (d - 2t)^2$ sq. ft. Water velocity = cu. ft. per sec. ÷ aggregate area per pass

$$= V = \frac{Q}{62 \times 3600 \times 0.00547\ n\ (d - 2t)^2} = \frac{Q}{1220\ n\ (d - 2t)^2},$$

$$\text{or, } n = \frac{Q}{1220\ V\ (d - 2t)^2} \ldots\ldots\ldots [6]$$

$$\text{Also, } S = \frac{\pi d}{12}\ nl, \text{ whence } l = \frac{3.83\ S}{dn} \ldots\ldots\ldots [7]$$

As an example, assume a unit of 2000 maximum i.hp. at 226 lb. throttle pressure and 27.68 in. vacuum, using 12.725 lb. of dry steam per i.hp-hr. Take the inlet water at 70 deg., outlet water at 95 deg. and water velocity at 8 ft. per sec.

By Equation [3], $p_s = 14.696 - 0.493\ (27.68 + 0.2) = 1.0$, whence t_s (from the steam table) is 102 deg. Then by Equation [4] the mean temperature difference is

$$t_m = \left(\frac{\frac{1}{8} \times 25}{32^{1/8} - 7^{1/8}}\right)^{8/7} = 16.64 \text{ deg.}$$

(Note that the arithmetical mean is 19.5 deg. and—by Equation [4a]—the logarithmic mean is 16.5 deg.)

At 226 lb. throttle pressure, $H' = 1200$. Since $h_s = 70$, Equation [2] gives

$$x\,L = 1200 - 70 - \frac{2545}{12.725} = 930 \text{ B.t.u.}$$

Then by Equation [1], $WxL = 12.725 \times 2000 \times 930 = 23,$-

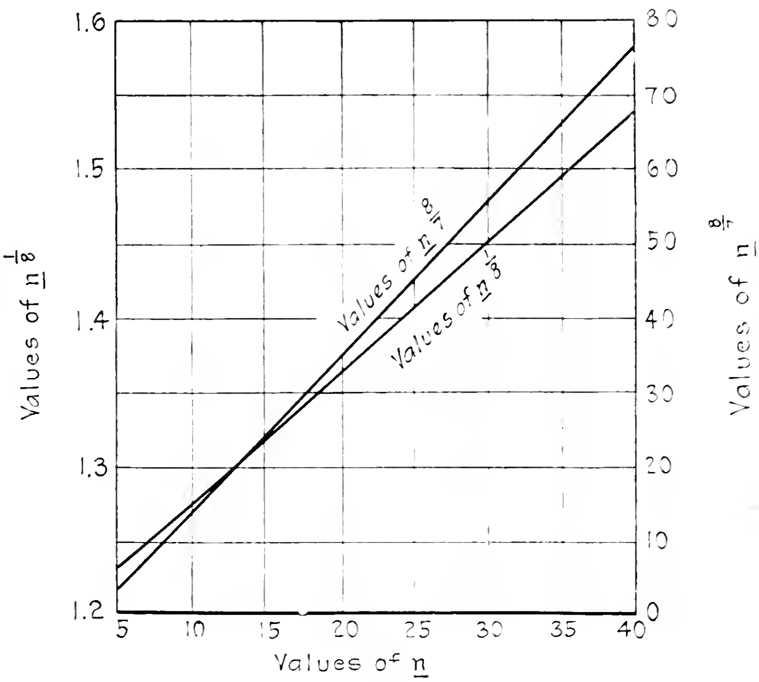

Fig. 2 Graph for Evaluation of Equations [4] and [5]

668,500 B.t.u. per hr. Setting this equal to $Q\ (t_1 - t_0)$, the weight of circulating water per hour is

$$Q = \frac{23,668,500}{95 - 70} = 946,740 \text{ lb.}$$

Equation [5] now gives the surface directly:

$$S = \frac{946,740}{40.63 \times 8^{0.6}} \left\{ (102 - 70)^{1/8} - (102 - 95)^{1/8} \right\}$$

$$= \frac{946,740 \times 0.2669}{40.63 \times 3.485} = 1780 \text{ sq. ft.}$$

If 1-in. No. 18 B.W.G. tubes are used, Equation [6] gives

$$n = \frac{946,740}{1220 \times 8\ (0.902)^2} = 119$$

as the number of tubes per pass. From Equation [7]

$$l = \frac{3.83 \times 1780}{1 \times 119} = 57.3 \text{ ft.}$$

This is the aggregate length of all passes. In the absence of certainty as to values of U and t_m, no effort is here made to choose a *best* ratio of l to d. Usual ratios are between 30 and 50, indicating that two passes will be desirable in this condenser.

(The value of U for these conditions works out $325 \times S^{0.8} \times 16.6 V^{0.5} = 796$.)

It is perhaps unreasonable to expect that definite and generally satisfactory values of U will ever be established. The transmission will inevitably decrease in service, the air richness influence is doubtful and the question of steam circulation has not been (perhaps cannot be) included. The rate of heat transmission in a surface condenser is a variable quantity, like the rate of transfer in a steam boiler. For safe design to meet anticipated operating conditions U should probably be taken at about 400, with due allowance for factors known to influence its value. Perhaps Weir's relation, $U = 250 V^{0.5}$, may be found safe if divided by a *hedging* factor of 2.

The mean temperature difference, which is only a slight factor in the determination of U, is itself a nearly linear factor in the total transfer. Accurate knowledge of its value is therefore of first importance. The weight of evidence points toward an exponential law for the rise of water temperature in the tube, but the logarithmic mean given by Equation [4*a*] represents very closely the result of such law for any ordinary conditions. Moreover, in Equation [1], exact values of the exponents are not fully settled.

A quick method for evaluation of Equations [4] and [5] is afforded by Fig. 2.

CLOSURE BY MR. ORROK

George A. Orrok. I am greatly pleased with the form which the discussion of the paper has taken. Professor Ennis has amplified the suggested method given in the paper by introducing factors which are usually slurred over. In the actual tests N was always known by the weight of circulating water times its temperature rise, and the steam was rarely wet, as it nearly always is in an actual condenser.

Mr. Stuart's discussion emphasizes some points which perhaps have not been brought out in sufficient detail. Mr. Kothny referred to my paper on Air in Surface Condensation (Trans.Am.Soc.M.E., vol. 34, p. 713) for data on air leakage, and I wish to reiterate again my statement that eternal vigilance is the price of freedom from air leakage. From 1 to 3 cu. ft. of free air per min, is very good practice with any commercial condenser, and this result can be obtained with condensers of the largest sizes.

Mr. Gibson mistakes K for U, and U is the coefficient of heat transmission in the fundamental formula $N = SU\theta$, while K is the reduced coefficient as given in Par. 10 $\left(K = \frac{U\theta^{.8}}{V_w^{0.5}} \right)$ with a further reduction for air richness.

A reference to Trans. Am.Soc.M.E., vol. 32, p. 1210, where the "three-dimensional" diagrams are shown, should make this distinction clear as well as Professor Ennis' question about the exponent (.8).

Mr. McBride brought up the very interesting point that frequently it is necessary to assume primarily the tube length and diameter in some commercial designs. I have met this case in my own practice a number of times, but have always solved it by trial and error instead of using the arithmetical mean.

Mr. Bancel has again brought up the question of the depth of the tube bank, and incidentally the velocity of the steam among the tubes. This is a very complicated subject, being mixed up with the prevalence of the water film on the steam side of the tubes. There has been some little mathematical work along these lines, but in our experiments the results were negative, as was also the case with the observed results on commercial condensers. At the present time, however, there seems to be no reason to doubt the statements regarding this subject in Trans.Am.Soc.M.E., vol. 32, p. 1160. Since writing the paper John E. Bell has read a paper on this subject before the Engineers' Society of Western Pennsylvania, in which he shows that a definite relation exists between the transfer rate and the cube root of the water condensed per hour per square foot divided by a function of the film temperature. More work is being done along these lines, but all I can say at present is that it is probable that we may be able to show a physical basis for the exponential formula of temperature rise.

A PROPOSED PLAN FOR THE ACTIVITIES OF THE MACHINE SHOP PRACTICE SUB-COMMITTEE OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, H. K. HATHAWAY

L. C. Brooks. While heartily indorsing Mr. Hathaway's attitude, I would point out that the electrical problem received no mention except in the fourth paragraph, where Mr. Hathaway advised a certain condition where the motor was overloaded. The policy of electric drive is becoming more and more prominent and is considered as a part of the installation. With proper investigation the following subjects would give valuable information to the public: The question of belt vs. electric drive, the advantages and limitations of individual drive or group drive, the horsepower required to drive, the relative advantages of individual drive for special machines, as planers, car-wheel lathes, etc.; in connection with electric drive, drum-type manual control vs. automatic control, dynamic brake as applied to electric control for certain machines, safety-first protection to the operator. In connection with Mr. Hathaway's tentative classification provision should be made for the question of operation, which is of vital importance.

CLOSURE BY MR. HATHAWAY

H. K. Hathaway. It is very gratifying that my suggested plan should have aroused so much interest, and that it should have been received so favorably. The Sub-Committee on Machine Shop Practice should, I believe, give careful thought to the utilization of existing committees, and in fact should take into account any existing agencies, either within or without the Society.

Mr. Pigott is right in pointing out that to accomplish results the committee must be handled more like an operating company than a council of advisers. To make this practical necessitates, as stated in my paper, a secretary who can devote his entire time and attention to the affairs of the committee, seeing that the program is carried out.

While it is desirable that ultimately the codified data on machine-shop practice should cover not only current practice but its development, it would, as Mr. Eberhardt suggests, be wise not to spend too much time in the beginning on the collection of data from papers and articles that have been published in the past, but to give particular attention to new material as it appears.

I regret that there should have been so much discussion as to the form of classification adopted, as while it is no doubt important that the best method of classifying be used, it is not nearly so important as that some form of classification be adopted, and it is still more important that some action be taken toward the carrying out of a definite plan leading to the further development of machine-shop practice as a science.

RELATION BETWEEN PERPETUAL-INVENTORY VALUE AND APPRAISAL VALUE, CHARLES PIEZ

HARRY BARKER.[1] The fundamental term "depreciation" has become so involved in a maze of differing definitions that even when engineers endeavor to use it quite technically it conveys different ideas to different persons. If we could agree on an acceptable vocabulary which we would employ in our discussions, a great gain would be made. Fallacies would be more quickly exposed and truths better comprehended.

I first endeavored about a year ago (in the proceedings of the Philadelphia Valuation Conference, held under the auspices of the Utilities Bureau) to harmonize some of these differences, and I desire here to draw attention to much the same ideas as then advanced.

The meanings which have been given to the term "depreciation" are seen to fall into two general classes: (*a*) losses in value of physical property, and (*b*) sums secured from earnings to offset loss in value of property.

The first group of definitions of "depreciation" can be further divided into: (1) aggregate actual or estimated loss in value from all causes; (2) the loss in value due to wear- and age-deterioration as distinguished from the loss of value from liability of obsoletion or inadequacy: and (3) the loss in value due to loss of ability to render full service or to decreased efficiency.

The second group is seen to be split into: (4) an annual accounting figure representing the depreciation for the year, or any other given period, deducted from gross earnings in computing probable true net earnings; (5) an annual sum used in making up the amount of necessary income to be secured by the rates. (This last is often an annual amount to be set aside out of the earnings to help create a reserve which will equal the cost of the several items of plant when they are retired from service and will pay for the renewals to the extent of the cost of the items retired. It might well be a direct repayment out of earnings of investment, equal to the annual loss in value of property due to depreciation.)

There is finally a sixth definition of depreciation as: Various aggregates of the annual sums secured from time to time to compensate for loss in value through deterioration or obsolescence, or both.

The several shades of meaning indicated in these definitions are sufficiently different to make our discussions run on diverging tracks. They show the need of greatly restricting our use of the word "depreciation." Our language is not so lean that we have to use one word in so many senses. Therefore I have a few propositions to advance.

The first definition—as the aggregate loss in value from wear-deterioration, inadequacy, supersession, antiquation, dilapidation, etc.—is probably the most used and the original one. This can well be adhered to, and a few available terms employed to carry the other meanings given.

The idea involved in the second definition makes a most useful distinction, which should be preserved, but it is more definitely indicated by "wear-deterioration," "age-deterioration" or "wear-and-age deterioration," according to the precise shade of meaning needed.

The third definition—loss in value due to diminished power to function or to decreased efficiency—has no real place in depreciation discussions, for mere ability to render the original service does not indicate lack of depreciation, and percentage of service ability (which is not the "serviceability" of the dictionary) alone does not measure value. (It indicates relative value only when the duration of that percentage of service ability is considered; if one machine can yield certain service for 10 years and a second machine can yield the same service for 20 years, their real values are not equal.) Instead of speaking of this loss of service ability as depreciation, it should be called "service-ability drop," or some equivalent.

The fourth definition has sprung up to give a short expression equivalent to "deductions for depreciation expense," or something like that. If there were not so many definitions in the field needing weeding out, its abbreviation to "depreciation" would be excusable. But, because of the confusion induced, the longer phrase should be reverted to.

Similarly in the case of the fifth definition, it is advisable to say "allowance for depreciation expense," or, more briefly, "depreciation allowance," and not merely "depreciation." Between speed of speech and accuracy of expression there should be no question of choice. Depreciation allowances correspond to what some engineers call a "theoretical depreciation" in contrast with what they designate as "actual depreciation" (meaning wear-deterioration) found by examination.

Definition five conveniently reduces to "renewal allowance," and for further simplicity to the coined word "renewance," which the speaker has found generally understandable. The first and the fifth definitions are perhaps the ones most used, so that it is a great advance to agree to speak of "depreciation" as the actual lost value, and "renewance" as one year's part of the compensation therefor.

However, it is little more than a convenient fiction to speak of building up reserves for renewals, since those funds have no relation to the amounts spent for the new equipments. Electric railways have been known to scrap generating stations and purchase power from central-station companies. In general, replacements are made with radically different equipment. What the business must be made to yield, in line with the Supreme Court's dictum, is full compensation to the utility concern for the loss in value of property from all the various causes already outlined. That is to say, the rates must cover the liability for retiring plant rather than the cost of renewing it.

"Retirance," therefore, has been substituted for "renewance." Retirance, then, is the annual amount to be repaid the corporation to compensate it for each year's depreciation. Retirance is a definite factor in rates, and in its nature is a repayment of invested capital. Unit retirance may be spoken of as a subdivision of retirance, as it has been apportioned over rates. Wear-retirance, age-retirance, obsoletion-retirance, etc., become useful special terms which can be accurately employed. The place of aggregate retirance is obvious.

By such a restriction as outlined on the employment of the terms "depreciation," "wear-deterioration," "depreciation-allowance," "retirance," etc., discussion is not appreciably encumbered and a fundamental cause of exasperating confusion is removed[2].

ROBERT J. HEARNE. The entire subject of physical valuation is bound up with proper cost-keeping and a perpetual inventory, and the greatest of these is the last. Properly kept, a perpetual inventory is a time saver and a daily corrector

[1] Associate Editor, Engineering News, 10th Ave. and 36th St., New York.

[2] Since this discussion was presented, the Valuation Committee of the American Society of Civil Engineers has made its final report; and in this the further useful distinction is drawn between "decretion" (reduction of service life), the cause, and depreciation (reduction of money value), the effect. Attention also should be here directed to the recent report of the Valuation Committee of the American Electric Railway Association in which a standardized list of 21 valuation terms, comprehensively defined, are recommended for use in place of the 300 odd terms now largely employed. (These terms were reprinted in Engineering News, Oct. 26, 1916.)—H. B.

on values and costs, and keeps everything up to date. It takes some trouble to install and some thought to keep going, but it pays.

I have had experience for nearly 15 years with a method that is adapted to almost any business. The business to which the method has been applied was established over 25 years ago, and includes importing, manufacturing small machinery, and dealing in supplies, so that the problems were numerous. To apply this method to a new business is very easy, and it can be applied to an old business a little at a time.

The inventory begins with the receipt of goods, either through purchase or manufacture, and a written invoice from the factory should be treated just as an invoice for purchases. Sales are deducted from inventory, of course, and so should be all tools and equipment which are worn out and junked. A written invoice for all goods junked is vital.

The proper classification of every article must be decided on in advance, and this should be done, as far as possible, in such a manner that each article will fall *naturally* into its class.

There are several grand divisions or classifications, namely:

(*a*) Furniture, Fixtures and Machinery. (Subject to deterioration.)

(*b*) Work in Process. (A proper shop-cost record is required to take care of this.)

(*c*) Merchandise, Supplies and Raw Material. (Generally figured at cost.)

Each grand division can be subdivided as often as experience shows it to be desirable.

In practice it has been found best to number each section. Symbols should be avoided. At first they seem helpful; in the end they are a nuisance. A numerical index is also essential, and it is easily kept. A number once used should never be used for another thing. Numerical and alphabetical indexing answer all purposes.

Physical control of stock is essential. Nothing should be received or given out without a voucher. If one is allowed to help himself to stock, without control, it is useless to attempt to keep a perpetual inventory.

The inventory items should all be on cards. Books are not practical, and a loose leaf is practically the same as a card, and not so serviceable.

A perpetual inventory is very helpful because it shows how goods move, and at what dates they sell, and will generally be more accurate than an actual counting of the goods. Nevertheless, a constant check is kept on the inventory by the simple method of actually counting stock on hand and reporting in writing on a "Goods Wanted Memorandum" before replacing any stock that is low. Any error in the inventory is thus discovered. In practice we have found that the inventory is the more reliable.

Keeping track of merchandise presents no serious difficulties, although most people still rely on the annual inventory. While it is true that Machinery, Fixtures and Tools must be appraised, yet an accurate description, accurate count, and accurate cost must be furnished before an appraisal can be made that is anything more than a guess.

Proper classification is very essential here. It is very wrong to attempt to value line shafting, belts and pulleys as a whole. Every pulley and belt belongs to some machine or to a line shaft, and should be so described in detail, not by guesswork. A separate inventory card should be kept for each line of shaft. The pulleys for driving machines, either directly or through countershafts, and the belts, are part of the driving equipment of each machine. This method simplifies the shafting, pulley and belting problem, as each belt pulley should be accurately described and priced on the inventory card for the machine it belongs to.

In classifying Machine Tool Equipment, only such equipment should be included with each machine as can be used only on that particular machine. For instance, if a number of screw machines exactly alike are used, then the spring chucks should be classified separately, and not as part of the equipment of any one machine. For the same reason milling cutters are not part of the equipment of any one machine.

Drills, taps, reamers and similar tools should always be separately classified. The more subdividing there is done, the easier it is.

Each machine tool should be listed in detail on a separate card, with a list of its equipment as originally bought, with dates and costs. New equipment can be added as bought or made. A proper addition is for freight, cartage and cost of installing, and of the pulleys and belts.

If costs are kept, say, on the right-hand side of the card, they can be totaled up, and the entire original cost shown at a glance. Estimates of present value can be written down, say, annually on the left side of the card in a column headed "Present Value," and dated.

Appraisal of present value can only be made by a competent, honest person who knows all the facts and is familiar with the business. Appraisals by outsiders are of little value. Taking off a fixed percentage per annum is unreliable. A simple test is to ask for how much cash would you be willing to part with the machine. Honestly applied, this test will give an accurate value. If we cannot assume intelligence and honesty, any appraisal is valueless.

In valuing small tools, such as reamers, taps, cutters, etc., no hard and fast rule can be laid down, but a few general principles will apply. In general, a stock of reamers and cutters in a shop will all be in use, hence all will be depreciated, but as worn-out tools are replaced it is a fair assumption that all are serviceable. A flat depreciation of, say, one-third would probably cover. With taps, drills and files, however, there would always be a large percentage, possibly one-third, which were unused, therefore a depreciation of, say, one-fourth would perhaps be correct. Equipment such as tote boxes and case-hardening boxes is subject to very great deterioration, and probably a depreciation of one-half would be right.

As to count of such items, it should not be guessed at. The rule should be that no tool should be junked until it is reported in writing to the office. The actual throwing out of junked tools should be done periodically, not daily, and no new equipment should be bought or made until an accurate count of that item is reported in writing to the office, for the purpose of checking off inventory.

For instance, if some number-size drills are wanted to replace stock, it is a simple matter to send a memorandum of tools on hand to the office. Inventory is then checked off. A new lot is ordered, and when they are received they are added to the corrected inventory. The worn-out tools are not generally charged to expense. This is taken care of by charging the replacement to expense. If no replacement is made, then the junked tools are charged to expense.

It is easy enough to keep track of the cost of a drawing, but the constant changes are difficult to analyze. It would be very wrong to keep all drawings and divide up the total cost among them. It is impossible to appraise their value. The best method is to keep them constantly weeded out. The inventory can be arranged numerically, using the same number for the drawing as for the part or machine. The same number

should also be used for patterns and special tools and jigs. Our practice is to keep track of original cost of drawing, and add 100 per cent. All drawings on inventory are priced. Drawings in actual use are carried at full price on inventory. Drawings which are not much used are carried at no value; if revived, the full value is restored; if obsolete, they are destroyed.

Patterns are kept track of numerically, a separate card for each. Patterns in general use are carried at full price. Those little used at no value. Obsolete patterns are destroyed. The pattern card is also made to serve as a record of cost of castings, and it is also noted if the pattern is in storage or at the foundry. In figuring the cost of patterns it is proper to figure all cost of making the first patterns. For instance, if a metal pattern is wanted, the first cost of the wooden pattern is figured in the cost of the final metal pattern, even though the wooden pattern is no longer of any use after the metal pattern is made. Alterations in patterns to get good castings are also considered a proper part of cost, but alterations in design are not.

Work in process is controlled by the fact that work is always started in lots or jobs, and time, material and overhead take care of this. Every piece of shop or repair work should be on a separate job ticket, unless very trivial. In this way all changes in equipment are kept track of.

Pipe, fittings and wiring in buildings can be classified and separated into mains and branches, just as suggested for shafting, belting and pulleys. Dead lines should be so marked and valued at practically nothing, but as dead lines are sometimes revived, it is well to keep track of them, unless they are actually abandoned.

In conclusion, it is important to have means of getting rid of all records, drawings, tools, etc. For this purpose a slip is used in which all possible places where there is a record are named, and all obsolete records are thus systematically destroyed. This includes patterns, jigs, drawings, catalogues, etc. If anything is discarded, but there is a possibility of revival, all records, tools, jigs, etc., are put in one box, and marked, for instance, "No. 1364—Section 13—obsolete," and stored away. In time actual junking will occur.

CLOSURE BY MR. PIEZ

Charles Piez. No schedule of depreciation, no matter how carefully and intelligently framed, will cover all possible conditions and provide for all possible contingencies. A fixed schedule is always lacking in that elasticity which would render it universally applicable, and must on that account be supplemented in unusual cases by exceptional treatment born of intelligent analysis and experience.

In discussing allowances to be made out of profits to cover loss or shrinkage of value, it is well to bear in mind that relatively few manufacturers regularly make such allowances for depreciation, and that even these few have never adopted, or even discussed any standard set of rates.

That loss of value from any one or all of the causes enumerated by Mr. Barker does occur is universally acknowledged. Academic definition of the generally used term depreciation does not stay its inroads on profits nor make the method of providing for these inroads any clearer. Why add such new terms as "retirance" and "renewance" to an already overburdened industrial vocabulary?

What is needed is a presentation of records and experiences, so that out of these we may develop a schedule of rates which can be looked upon as a standard for determining annual allowances against loss of value due to wear-and-age deterioration and obsolescence.

The loss of value is legitimately a part of the cost of the output, a fact which is at present overlooked in many business enterprises; and to correct this omission or oversight, it is to my mind much more effective to start with a sane schedule of rates of depreciation than to start with a definition. I realize, of course, that Mr. Barker's discussion pertains more particularly to the valuation of public-utility properties, where the allowances to be made on individual units may be so large as to justify division into several classes or causes; but in the mechanical industries the terms "annual depreciation" and "total depreciation" contracted from "annual depreciation allowance" and "total depreciation allowance," are so widely understood as to require no further definition.

What is needed is to have some association of the importance and prestige of this Society investigate this subject and recommend a schedule of rates of annual depreciation for adoption.

With the administration proposing a further tax of five per cent on all profits in excess of eight per cent on the investment, isn't it necessary that the engineering societies shall define what so important a factor in the expense of production as depreciation amounts to annually and how provision for it shall be made out of profits?

Mr. Hearne has outlined very clearly a system by means of which a perpetual inventory of work in process, as well as of the other assets of a manufacturing plant, can be introduced and maintained.

I am a strong advocate of the value of running or perpetual inventories for work in process and materials in stores, as well as for buildings and equipment, and Mr. Hearne's discussion is valued because it outlines the possibilities in these directions. In the valuation of small tools I believe it safer and nearer to the truth to assume that this equipment averages about halfway between new and worn out, and to charge off a flat depreciation of 50 per cent instead of a third. I believe his method of valuing active patterns at full cost is dangerous, and the same must be said of his practice in respect to drawings.

I have never heard of purchasing drawings at anything more than a merely nominal sum upon the liquidation of an industry, and patterns in the average industry are subject to such marked deterioration in value through obsolescence as to justify the flat rates of depreciation named in the schedule.

MECHANICAL DESIGN OF ELECTRIC LOCOMOTIVES, A. F. BATCHELDER

George Gibbs. I take it that Mr. Batchelder's paper is not intended to be more than a very general statement of certain features which must be taken into account in the design of an electric locomotive, together with certain conclusions which he is led to make from his study of the problem. It may therefore be in order for me to give briefly some opinions of my own, and in so doing I am sorry if I must disagree with the conclusions in some respects.

A complete presentation of the subject of electric-locomotive design has yet to be made; all we can do at present is to chronicle experience with various types and classes in different services. Unfortunately the total number actually in service is quite limited and the period over which our experience runs is also in many cases short.

In the first electric locomotives built not so many years ago the chief consideration was to get a machine which would run and pull a train without continually breaking down through some electrical defect; this is the first step in a young art.

When these conditions were satisfied, it then became a question of obtaining the best design from the standpoints of safety, efficiency and low maintenance cost. This second stage is still under way and the end is by no means yet attained, nor can this be expected any more than has been the case with the steam locomotive, in which there has been a tremendous improvement during the last ten years in increased capacity and efficiency.

Many years' experience in testing work for railroads has brought me into very close touch not only with the design of locomotives but of track. I early became impressed with the importance of high center of gravity in steam locomotives and with the importance of reducing the dead weight below springs to the lowest consistent amount. The track structure does not present a perfect and unyielding plane surface; it has defects, both in alignment and surface, and it is elastic. Its elasticity is a saving characteristic as regards safety and the low maintenance cost of track and equipment. Therefore, a locomotive in running over the track has set up in it oscillations and movements, the effects of which become important not only to the locomotive structure but to track, as regards safety and cost of maintenance.

These conditions are well understood in steam-locomotive practice but, unless we are careful, are likely to be lost sight of in designing electric locomotives, where the radical difference in the application of the motive power suggests or permits a variety of wheel arrangements, weight distribution, etc. I cannot here go into a full discussion of this important point, but I can say generally that the elimination of reciprocating parts from the locomotive, a result accomplished in electric locomotives but impossible with steam, does not warrant us in abandoning some of the very important principles well demonstrated in steam practice, namely, that for safe and successful operation under average track conditions, high center of gravity, least dead weight below spring supports and an unsymmetrical wheel and weight distribution give best results. The above applies especially to high-speed operation; for low speeds similar arrangements are also desirable but not so essential.

A word more about the height of center of gravity. There seems to be a tendency to consider that the center of gravity of the machine as a whole is the only consideration of importance, and some electrical designers have been content to secure a fairly high center of gravity by the combination of heavy apparatus in the cab of the locomotive (this being above the springs), with heavy weights carried on the axles or below the tops of the wheels. This arrangement does not give the equivalent of a given height of center of gravity in a steam locomotive (where the bulk of the weight is above springs), as regards the effect on track. A steam locomotive has dead weight only of the driving wheels, axles and boxes; all other weights are spring-borne and thus are not only eased from vertical shock on the track but by the rolling of the mass on the springs tend to effectively relieve lateral rail pressures and convert them into vertical, a condition which conduces greatly to safety and reduction in maintenance both of locomotives and track structure.

The writer, a number of years ago, in taking up the design of electric locomotives for the Pennsylvania Terminal in New York, suggested a method of making an extensive series of experiments to determine the riding qualities of different types of locomotives. The procedure took the form of tests on an experimental stretch of track which was made movable transversely by having the rails mounted on rollers and the transverse motion restrained by stops consisting of hardened-steel points or balls set up against steel strips which, by indentation, register the tendency to displace the track laterally. It was intended by this means to measure the tendency of certain wheel arrangements in locomotives to set up rhythmic side motion and also to register the throw sidewise by defects in track surface. As the result of these tests we obtained much valuable information regarding design of electric locomotives confirmatory of the general principles I have mentioned above, showing the value of an unsymmetrical wheel base for an electric locomotive with a high spring-borne center of gravity and low dead-weight component. I believe a more extensive series of these tests, and an acquaintance with the results by electric-locomotive designers, would accomplish a valuable purpose in clearing up many existing differences of opinion.

Mr. Batchelder speaks of wheel arrangement and height of center of gravity as affecting locomotive design; I am unable to follow his reasoning and, if I understand him, I do not agree with his conclusions. He appears to be trying to make out the case that high center of gravity is unnecessary if you have leading trucks for the locomotive, and that the presence of leading trucks makes it immaterial where the motors are mounted; with these conclusions I disagree. Furthermore, he appears to conclude that a leading truck is essential for high-speed operation by stating that steam locomotives cannot be safely operated backward at high speed. It is common in steam practice abroad, and not unusual in suburban practice in this country, to run steam locomotives backward without leading trucks, i.e., the American type of locomotive. In such service steam locomotives are frequently run at quite high speeds on roads having much curvature. Abroad, especially in England, it is not unusual practice to so operate them over long distances at high speeds. The real objections to the operation of steam locomotives backward are, in the first place, that the view of the enginemen is not good, secondly, that the tender is a short-wheel-base structure having a variable and shifting load, and thirdly, that coal dust which is thrown about becomes very disagreeable to the enginemen. However, I believe that leading trucks are useful in locomotive practice, and favor them, but I simply mention the above to indicate that they are not a necessity for safety.

Mr. Batchelder appears to conclude that simplicity, adaptability, reliability and efficiency require that electric locomotives must be standardized in design in the direction of placing the motive power on the trucks, either geared or gearless motors, and would obtain the requisite power by coupling trucks with short wheel base together, also that this type of locomotive can be used in either high- or low-speed service by simply changing the gear ratio. This procedure is doubtless desirable from the manufacturer's and also from the user's standpoint, if it can be done, as it results in one type of locomotive for any service, but there is no indication, from my experience, that electric motive power puts us any nearer this desirable end than does steam motive power. It certainly seems a mistake for engineers in this early stage of heavy electric-railroading development to come to the hasty conclusion that one standard type of electric locomotive must be advocated for every service, especially when experience in the operation of steam as well as electric locomotives seems to indicate the desirability of combining the elements as I have before indicated to obtain best tracking results.

It must be remembered that track maintenance is a very large item in the cost of operating the railroad, and that track on the average railroad is not always in the best physical condition; therefore the locomotive designer should coöperate

with the track department and not proceed independently in developing the best type of locomotive for any particular local conditions. I should put the prime considerations in determining the serviceability of an electric locomotive as follows:

It should have capacity for the given service.

Electrically and mechanically it should be operative.

It should be least destructive to track, especially when track is not usually kept in perfect surface.

Simplicity and low cost of maintenance.

Low first cost.

For high-speed service especially I would reverse the order which Mr. Batchelder gives under the heading Power Efficiency, for the different manners of mounting motors and connecting them to the driving axles.

In concluding, Mr. Batchelder suggests that it would be interesting to "see a complete investigation of different types of locomotives that are now operating in the same kind of service of different railway terminals in New York City, etc." This certainly would be interesting and should be valuable. I have repeatedly urged such a comparison and suggested that it include not only a comparison of the actual upkeep of the locomotives but should be made to bring out the relative overall upkeep of the railroad. The experimental form of track I have before alluded to could probably be made available for experiments by the coöperation of the various railroads interested if we could secure some concerted action looking to the inauguration of a series of tests. We know now, from figures obtained over a number of years, that there is practically no difference in the cost of locomotive upkeep between such widely divergent types, for instance, as the New York Central and the Pennsylvania Terminal locomotives, and it would therefore be useful to bring out clearly by test what other differences, if any, there are in overall adaptability to influence the future design of a form of motive power of growing importance.

C. H. Quereau.[1] In the main I agree with the conclusions reached. However, it seems to me very unfortunate that this paper, as well as others recently presented, is a general statement of the conclusions of the author rather than a statement of accomplished results. There should now be available accurate figures based on actual operation, which should not be held back because of mistaken ideas on the part of those who have the facts or those who have the authority to make them public. That Mr. Batchelder appreciates this, is shown by the last paragraph of his paper.

In Mr. Batchelder's paper, in the list of features arranged in the order of their importance, I would add "Maintenance" under Item 4. It would then read "Convenience of Arrangement as Affecting Safety, Efficiency of Operation and Maintenance." It is quite probable that convenience of maintenance was in the author's mind, but it seems to me of sufficient importance to be mentioned specifically.

In the discussion under the heading "Safety of Operation," I must confess that I cannot quite follow, probably because I do not clearly understand what was written, or have not the information on which the author bases his discussion. For instance, in describing the action of a locomotive having two driving axles guided by a two-axle swivel truck when entering a curve the statement is made that "The flange of the leading wheel gradually comes in contact with the outer rail, giving the guiding truck an angular motion about its outer rear wheel." I have believed that the angular motion of a four-wheeled truck was about its inner rear wheel, the fact being that when a truck is on a curve the outer-forward-wheel flange and the inner-rear-wheel flange are against the rail, the other two flanges not touching the rail. I do not see, however, that this difference is of particular moment and bring it up only that the matter may be discussed and clearly understood.

I believe it will be generally agreed that the operating advantages gained by having electric locomotives designed to operate in either direction is of so great importance that means must be found to provide satisfactory designs to meet this condition, notwithstanding the fact that the effect of the trailing engine truck contributes to unstable riding of the engine. The paper proposes to prevent this oscillation by the introduction of resistance against swiveling. This is practicable and has been so demonstrated, but results in increased flange wear, at least when the center of gravity is low.

As to reliability in service, we have had a number of papers describing the operation of electric locomotives on steam railroads, the design of the locomotives and the description of power plants and transmission lines, but reliability in service usually has been overlooked. In eastern territories, especially around the large cities, a delay of a very few minutes will upset the smooth operation of the railroad for hours and the effect of it reach back on the line for 150 miles. The prevention of such delays is worth considerable increase in first cost, and the maintenance methods should be such as to prevent delays practically regardless of cost; it is decidedly poor policy to reduce maintenance costs if by so doing the result is increased delays.

Mr. Batchelder very wisely considers the cost of maintenance of permanent way of more importance than cost of maintenance of locomotives. It is extremely difficult to state definitely what, if any, effect the electric equipment has on the cost of maintenance of permanent way. If the cost of maintenance of way is no greater under electric than under steam operation, such a condition would undoubtedly not be used as an argument against electrification.

As to the cost of maintenance of electric locomotives, the difference in cost-of-maintenance charges at the rate of 3.5 cents a mile and seven cents a mile may be safely figured as not less than $1000 per engine per year. This saving, capitalized, represents a considerable sum, and would warrant an appreciable increase in first cost to secure it.

In discussing a paper on the mechanical design of electric locomotives we must recognize the fact that there is no common fund of experience or knowledge from which to draw evidence in reaching conclusions, as there is concerning steam locomotives. Opinions and theories are essential in designing radically new electric equipment, but only conclusions based on extended service results are authoritative. No one has had the advantage of experience with more than one type, therefore, one's conclusions as to other types are based on opinions and theoretical considerations rather than actual results as shown by service records.

So far as I know the published data on service results are very limited, either as to first cost or maintenance or reliability in service as shown by train-delay statistics, and therefore each person will place the emphasis on some particular feature, rather than considering results as a whole. If it were possible for this Society, as a neutral, to obtain statistics covering the main points as to results in service, extending over several years, and make them public, it would be of very decided value.

[1] Superintendent of Electric Equipment, N. Y. Central R. R., New York.

The New York Central electric locomotives are all equipped with bi-polar, gearless motors mounted directly on the driving axles. The operating results have been completely satisfactory to the officials of every operating department affected. This statement does not include the net financial returns from the investment, which must take into account the item of fixed charges. With the usual maintenance these locomotives ride satisfactorily and without undue effect on the track structure, and are perceptibly more comfortable than steam locomotives. In order to secure these results it is necessary to keep the total lateral motion, both in the boxes and center pins, within three-quarters of the allowable lateral motion on steam locomotives. Table 1 contains statistics which will permit a personal conclusion as to the reliability of these locomotives in service, which will probably be more satisfactory than any expression of opinion.

TABLE 1 TRAIN DETENTIONS DUE TO DEFECTS IN ELECTRIC LOCOMOTIVES

	Miles Per Detention—All Locomotives		
Year	Mechanical	Electrical	Grand Total
1912	48271	103967	32965
1913	27873	86716	21093
1914	35625	57395	21981
1915	53720	107440	35813
	Type S Locomotives		
1915	59583	187260	45201

NOTE: All detentions of two minutes or more included. In 1913 and 1914 there was a total of sixteen Class T locomotives placed in service. In 1912 there were 47 locomotives in service. Since the middle of 1914 there have been 63. Detentions due to man failure, or delays to following trains, not included.

In this connection I wish to enter a strong plea for the use of Miles per Detention instead of Miles per Minute Detention as the unit in the preparation of statistics by which to judge the reliability of equipment in service and the efficiency of the organization responsible for maintaining it. Including the time element leads only to confusion.

TABLE 2 INSPECTION AND REPAIRS OF ELECTRIC LOCOMOTIVES

	Cost, Cents per Mile		
Year	Labor	Material	Total
1912	1.888	1.460	3.348
1913	1.982	1.454	3.436
1914	2.155	2.134	4.286
1915	1.901	1.379	3.280

NOTE: The above statistics were compiled in accordance with the requirements of the Interstate Commerce Commission. In the year 1914 it was necessary to replace all driving-wheel tires because of unsuitable material, regardless of the extent to which they had been worn. The costs of maintenance have been essentially as above since 1907, omitting 1914.

The figures in Table 2 include the cost of inspection and maintenance of all the electric locomotives, both road and switch. In 1912 and 1913 approximately half the total engine mileage and in 1914 and 1915 approximately one-third was that of engines used in switching service. The cost of maintenance of engines in switching service is about twice that of those used exclusively in road service. It follows that the cost of maintaining the road locomotives has been about 2.5 cents per mile and that of the switch engines about 4.8 cents per miles. These engines were not designed for switching service; bearing this in mind, they have given remarkable results.

For the first ten months of 1916 the average cost of maintenance of all the electric locomotives has been 2.73 cents per mile. This gives a cost of approximately four cents per mile for the locomotives in the switching service and approximately two cents per mile for those in road service. I expect these costs will not be exceeded for the entire year 1916, but very much doubt that we will be able to keep the maintenance costs permanently at this level.

CLOSURE OF MR. BATCHELDER

A. F. BATCHELDER. One point I want to bring out is the desirability of having more weight on the rail at the place of the thrust. That place, by actual test, is at the rear truck. That is not from guesswork, or from theory, or from calculation, but actual fact, tested and observed for 50,000 miles of running, for the particular purpose of finding out the effect of a double-end locomotive on the track. I have witnessed rails displaced three-quarters of an inch by the rear truck when the leading truck did not appear to move the rail at all. The speed at this time was in the neighborhood of 80 m.p.h.

The double-end locomotives I have seen run did not oscillate from side to side when running on curved track, but would hug one side or the other and ride steady; on tangent track, however, they would oscillate from side to side, except when the truck was held from swiveling in the track, in which case the locomotive would run steady just as it did on the curves.

Regarding Mr. Fowler's tests, they seem to agree with the paper, as the steam locomotive with its rigid frame carried directly on springs and with its center of gravity the same height as the car carried on low center pins, did not give as great a thrust. The car would give the effect of a low center of gravity because the side thrust was taken first against the center pin which was relatively low, resulting in less vertical pressure, while the locomotive has a greater vertical pressure due to the side thrust being taken directly and down through the side springs to the rail.

I have never seen any trouble on a curve with double-end locomotives except where too large resistance was used against the trucks curving. A double-end engine, according to my experience, is absolutely smooth and good running on a properly elevated curve.

In regard to Mr. Quereau's remarks as to the pivot point of a truck, I would say that I have not made tests to determine this, but as the outer wheels are heavier, due to the centrifugal and curving forces applied at the center pin, I have assumed that it would pivot about the heavier wheel.

I am gratified to note that Mr. Quereau has furnished figures which bear witness favoring locomotives of the simple and efficient design, and hope that these figures and what Mr. Quereau has to say about the operation and maintenance of these locomotives will have careful consideration by those interested. Mr. Quereau has spoken about the resistance tending to prevent the guiding trucks from oscillating results in increased flange wear, and I believe that Mr. Quereau is right. With the engines Mr. Quereau has in mind, there is a frictional resistance of an amount that once the truck has taken a position some external force is required to put it into another position, and it might therefore run cock-eyed on the track and cause flange wear. In that particular case flange wear is much preferable to oscillation.

Mr. Katte has spoken of coil springs on the journal boxes, and I would add that my experience with them has been gratifying.

Mr. Young has understood me to say that a locomotive will not run backward safely. I would rather modify that statement and say that it is not desirable to run it backward. For that matter, I do not know of any locomotives of the American type operating at 80 m.p.h. backward.

Mr. Eveleth has been associated with me throughout a large portion of his experience with electric locomotives, and his discussion favors the conclusion of the paper.

Replying to Mr. Gibbs's written discussion, I would say

that Mr. Gibbs seems to agree with me as to the importance of the high center of gravity in steam locomotives; however, it seems to be an inherent condition in steam locomotives, and if it were not desirable it would be difficult and expensive to reduce it any considerable amount.

It is also desirable to have the dead weight below the springs as little as possible, especially in steam locomotives where the unbalancing, due to reciprocating parts, adds relatively large values to the vertical impact. It is not uncommon in well-designed high-speed steam locomotives to have the dead weight on some axles 13,000 or 14,000 lb., and to this is added the effect of the unbalancing, due to the reciprocating parts. A careful analysis of this will show that these values are considerably in excess of the dead-weight values on high-speed electric locomotives of the design suggested in the paper as best adapted for this service, which has been built up to the present time. The last locomotives of this type built for the New York Central R.R. to handle 1200-ton trains at 60 m.p.h. has a maximum of 6310 lb. dead weight per axle.

Again Mr. Gibbs agrees with me in that we should not abandon any of the important principles that have been found good in steam practice. I would add, however, providing it is possible to retain the principle in its desirable form. I believe the paper has made it clear that the high center of gravity cannot be used to the same advantage in double-end-operating locomotives with trailing trucks as with a single-end steam locomotive, unless special provision is made in the design of the truck, in which case it matters not whether the center of gravity is high or low.

Relative to the unsymmetrical wheel and weight distribution in double-end-operating locomotives, I am unprepared to agree or disagree with Mr. Gibbs, but, offhand, I would say that within the possibilities of locating the weights, the effect would be slight and could be easily overcome by the design of the guiding trucks.

As to Mr. Gibbs's "A word more about the high center of gravity," and how electrical designers secure the high center of gravity, I wish to repeat that it does not make any difference whether the center of gravity be high or low, or how it is obtained, if the locomotive is provided with guiding trucks at each end (the locomotive is guided at its ends and not in the middle), and, as stated in the paper, the trucks can be designed to obtain the results required.

The testing device that Mr. Gibbs describes is extremely interesting and very valuable in determining certain characteristics, such as the transverse movement required in the trucks and measuring the transverse pressures tending to displace the rail, but it does not determine whether or no the locomotive is destructive to the track or safe to operate, as it makes no record of the vertical pressure which affects the adhesion between the rail and tie, which Mr. Gibbs apparently deems important and which I believe is one of the most important features to be obtained.

It is not the intention of the paper to convey the idea that it is necessary to have leading trucks for the successful high-speed locomotive, but to say that with leading trucks the desired results can be obtained.

Relative to the desirability of operating single-end locomotives backward, I am quite content to leave this with those who have had experience in operating.

Relative to gearing locomotives to obtain satisfactory results for high- or low-speed service, I would say that this is done very effectively on several roads, and the results indicate that it is very good practice.

THE FLOW OF STEAM AND AIR THROUGH ORIFICES, HERBERT B. REYNOLDS

G. B. UPTON. Inspection of the paper as to conditions of measurement shows (1) that pressures were taken in the dead eddies close to the orifice plate, above and below; (2) that orifices were small compared to pipe diameter, the largest ratio being with a ½-in.-diameter orifice in a 2-in. pipe; (3) and that pressure drops were large, generally all or nearly all of the excess of pressure P_1 above atmosphere being used to cause flow. The author did not touch, nor intend to touch, on the experimental case of a thin-plate orifice, large compared to pipe and pressure drop small compared to initial pressure, that is, the conditions which would make the thin-plate orifice a competitor of the venturi tube as a measuring device.

The usual formula for flow of gases or vapors through a venturi is

$$W = C F_2\left(\delta_0\frac{T_0\, 2gy}{P_0(y-1)}\right)^{1/2}\left(\frac{P_1}{T_1^{1/2}}\right)\left\{\frac{(1-x)^{2/y}-(1-x)^{(y+1)/y}}{1-a\,(1-x)^{2/y}}\right\}^{1/2} \quad [1]$$

In this equation the units are in the foot-pound-second system. W is the flow in pounds per second; C the "coefficient" of the venturi; F_2 the area of the throat of the venturi; δ the density in pounds per cubic foot; y the ratio of specific heats at constant pressure and constant volume for the gas or vapor; x the ratio of the "venturi head" (or drop in pressure from entrance to throat of the venturi) to the driving pressure at entrance, or $x = \Delta P/P_1 = (P_1 - P_2)/P_1$; and a the square of the area ratio F_2/F_1. Subscripts 0 refer to standard conditions for the gas; subscripts 1 and 2 to entrance and throat of the venturi, respectively.

In an article by the discussor in the *Sibley Journal of Engineering* for December, 1914, pp. 90-95, it was shown that the venturi formula [1] could be replaced by

$$W = C F_2\left\{\frac{2g\ \delta_0\, T_0}{P_0(1-a)}\right\}^{1/2}\left\{\frac{P_1\cdot\Delta P}{T_1}\right\}^{1/2}\left\{1-\frac{3+a}{4y(1-a)}\cdot\frac{\Delta P}{P_1}\right\} \quad \ldots [2]$$

or

$$W = C F_2\left\{\frac{2g\ \delta_0\, T_0}{P_0(1-a)}\right\}^{1/2}\left\{\frac{P_1\cdot\Delta P}{T_1}\right\}^{1/2}\left\{1-\frac{(3+a)}{2y(1-a)}\cdot\frac{\Delta P}{P_1}\right\}^{1/2} \quad [3]$$

The accuracy of this simplified formula was shown to be within one per cent, even for the largest values of $\Delta P/P_1$, if we remember the "critical" value of P_2 with regard to P_1 for gas expansion, and the variation of nozzle coefficients with flow when ΔP is large compared with P_1.

To compares equation [3] with that of Reynolds, we must change to the same units. W of [3] changes to Q of Reynolds' formula by multiplication by 60 δ_0. P and ΔP values of [3] change to corresponding values of Reynolds' formula by multiplication by 144. F_2 of [3] must be multiplied by 144 to reduce to inches. C may be taken as unity. δ_0 for air = 0.0807: T_0 = 492 deg. fahr.: P_0 = 14.7, and $\sqrt{(2g)}$ = 8.02. Hence the reduced formula obtained from [3] is

$$Q = \frac{816\, F_2}{\sqrt{1-a}}\left\{\frac{P_1\cdot\Delta P}{T_1}\right\}^{1/2}\left\{1-\frac{(3+a)}{2y(1-a)}\cdot\frac{\Delta P}{P_1}\right\}^{1/2} \quad \ldots [4]$$

The orifices used by Reynolds ranged from ⅛ in. to ½ in. in diameter, in 1½-in. or 2-in. pipes. Taking a 3/16-in. orifice in 2-in. pipe as typical, the ratio of orifice area to pipe area is $(3/32)^2$. There is a contraction of area of the flow beyond the thin-plate orifice, on the low-pressure side, with a "contraction coefficient" (K) which most probably lies near 0.60, and must be between 0.60 and 1.00. The reason that we cannot take K as 0.60 is that when the pressures are measured, as Reynolds did, close up to the orifice plate, the pressure drop

is slightly less than it it were taken exactly at the section of minimum area of flow below the orifice. This smaller pressure drop we compensate for in our calculations by using a value of K larger than its true value, which is somewhere near 0.60. The effective value of K may be 0.70 or 0.80.

It is the contracted flow beyond the thin plate orifice which really corresponds to the throat of a venturi. The area ratio from pipe size to throat size is $K(3/32)$; and assuming $K = 0.75$, the factor a in the venturi formula is $0.75^2 (3/32)^4 = 0.000043$. This is so near to zero as to be negligible. The value of γ for air is 1.40, under ordinary pressures and temperatures. On account of the contraction of flow beyond the orifice the value of F in the venturi formula is KA, A being the area of the orifice. With these values inserted in formula [4] it becomes

$$\left.\begin{aligned} Q &= 816\,KA\left\{\frac{P_1\,\Delta P}{T_1}\right\}^{1/2}\left\{1-\frac{3.00}{2\times 1.40}\cdot\frac{\Delta P}{P_1}\right\}^{1/2} \text{ or} \\ Q &= \frac{816\,KA}{\sqrt{T_1}}\left\{P_1(P_1-P_2)\left(1-1.072\,\frac{(P_1-P_2)}{P_1}\right)\right\}^{1/2} \text{ or} \\ Q &= \frac{816\,KA}{\sqrt{T_1}}\left\{(P_1-P_2)(-0.072\,P_1+1.072\,P_2)\right\}^{1/2} \end{aligned}\right\} \quad \ldots[5]$$

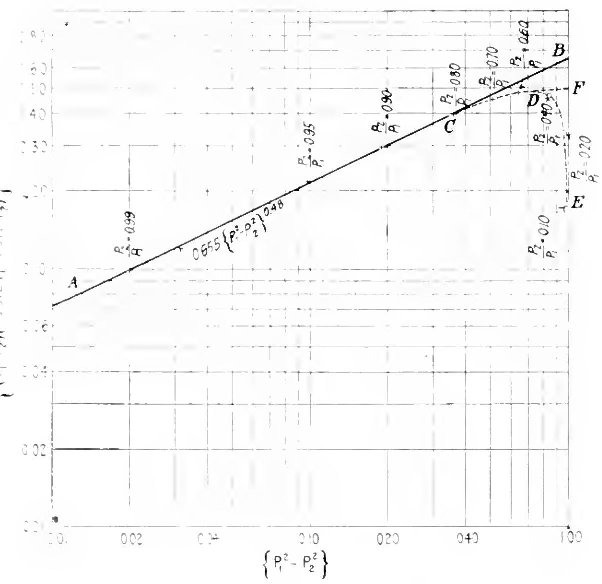

Fig. 1 Comparison of Reynolds and Venturi Formulae

The expression $\{(P_1-P_2)(-0.072\,P_1+1.072\,P_2)\}^{1/2}$ is obviously not convertible by algebraic transformation into anything much like Reynolds' expression $(P_1^2-P_2^2)^{0.48}$, which may be written for comparison as $\{(P_1-P_2)(P_1+P_2)\}^{1/2}$. Dropping the attempt to make a direct conversion of one formula into the other, we may test to see whether there is some constant ratio between the two expressions $\{(P_1-P_2)(-0.072\,P_1+1.072\,P_2)\}^{1/2}$ and $(P_1^2-P_2^2)^{0.48}$. Table 1 and Fig. 1 show the comparison and its results.

The figures in Table 1 are plotted in Fig. 1. The line AB has the equation $0.655\,(P_1^2-P_2^2)^{0.48}$. Up to the point C it fits nicely the values calculated from the modified venturi equation. The venturi values then go down CDE; but the venturi equation is here wrong because the values of P_2 are below the critical. The actual values would follow out the general direction CDF rather than CDE. If we remember that the contraction coefficient of the orifice is a function of P_1 and (P_1-P_2), it will be evident that the expression $0.655\,(P_1^2-P_2^2)^{0.48}$ may be a very good fit to experimental values of flow throughout the entire range of pressure and pressure-drop values.

Putting the expression $0.655\,(P_1^2-P_2^2)^{0.48}$ in place of $\{(P_1-P_2)(-0.072\,P_1+1.072\,P_2)\}^{1/2}$ in equation [5], there results

$$Q=\frac{0.655\times 816\,KA}{\sqrt{T_1}}\left\{P_1^2-P_2^2\right\}^{0.48}=\frac{534\,KA}{\sqrt{T_1}}\left\{P_1^2-P_2^2\right\}^{0.48} \quad \ldots[6]$$

Reynolds' expression makes the coefficient of A to be 405. For this to be so, it is necessary that K have the value $405/534 = 0.758$, which, as has been pointed out above, is both possible and reasonable. The conclusion is that Reynolds' empirical formula agrees as well as can be expected with the mathematical calculations of the flow of air under the circumstances of his measurements.

TABLE 1 COMPARISON OF REYNOLDS AND VENTURI FORMULAE

Argument, P_2 (P_1 taken as unity)	Values of expressions		Ratio	Remarks
	$[(P_1-P_2)(-0.072\,P_1+1.072\,P_2)]^{1/2}$	$(P_1^2-P_2^2)^{0.48}$

CLASP BRAKES FOR HEAVY PASSENGER EQUIPMENT CARS. T. L. BURTON

O. C. Cromwell. In about 1912 the Baltimore & Ohio Railroad, along with other railroads, began to replace wooden passenger-equipment cars with all-steel cars of greater length and heavier weight, and with these cars more or less difficulty was experienced in the proper controlling of the speed and braking of the trains, necessitating very close and frequent adjustment of the brake apparatus on the trucks.

In 1914 the Baltimore & Ohio Railroad again purchased a number of passenger-equipment cars, including 60-ft. steel smokers with 4-wheel cast-steel trucks, steel coaches, passenger and baggage, baggage and mail and baggage cars with 6-wheel cast-steel trucks and weighing about 135,000 lb., and 73-ft. dining cars weighing about 157,000 lb. Clasp brakes were applied, and the clasp brake is now considered the standard brake for this class of equipment.

As passenger equipment cars become larger, the question of increasing the size of cylinders and the brake apparatus has become quite a serious one. Relief has been found in the use of clasp brake, in that while an 18-in. diameter cylinder may be used on cars with maximum weight of 143,000 lb. with single-shoe brake-beam type of truck, however, with clasp brakes a maximum weight of 153,000 lb. is allowed.

The clasp brake prevents the rapid accumulation of piston travel and consequently enables a larger-diameter cylinder to be used. The old-style brake with a standing piston travel of 6 in. has a running travel of 7½ in., a difference of 1½ in.,

while the clasp brake with a standing travel of 6 in. has a running travel of 6¾ in., a difference of ¾ in.

The location of the shoe of the clasp brake in relation to the wheel, namely on the horizontal center line, prevents the rapid accumulation of slack, and consequently piston travel, while the old-style brake beam with the single shoe located some distance below the center line caused rapid wear and accumulation of slack which was reflected in the piston travel.

With the single-shoe brake beams on the heavier trains on long grades, when the brake shoes were wearing thin, the shoes have been found fused to the heads due to the heat generated by the long application of brakes. This condition does not obtain with the clasp brake.

With the clasp brake journal bearings wear more uniformly and do not crowd to the side, as in the case of single-shoe brakes. It has also been found with the clasp brake that there is less wear on the pedestal jaws and the journal boxes and the shoes, and when starting out from a terminal shoes can be permitted to go on a run worn as much as ¼ in. thinner than in the case of the single-shoe application. We feel that on the heavier-passenger-equipment cars the clasp brake will shortly be found in almost universal use.

The reduction in the number of hot boxes on passenger-train cars which has taken place since the application of clasp brakes is not claimed to be due wholly to the clasp brake, but it has contributed its share to the improvement.

B. P. FLORY. The conclusions which are arrived at in the paper are borne out by practical experience of roads which have cars equipped with clasp brakes in service. On the New York, Ontario & Western Railway we have 12 all-steel cars weighing 106,000 lb. with four-wheel trucks equipped with clasp brakes since May, 1914. There has been no trouble experienced in the operation of the brakes on these cars and we have noticed all of the things to which Mr. Burton calls attention. These cars run in train with other cars which have the single brake, and the difference in riding of the cars when stopped is very noticeable.

As to hot boxes, we find that for a period of 30 months, the cars making in that time a mileage of 1,873,500, there have been 10 hot boxes, mostly due to new wheels and axles. During the same period the balance of our passenger cars had 88 hot boxes with a mileage of 11,507,200, or an average of 130,769 miles per hot box against an average of 187,350 miles for the cars equipped with clasp brakes.

Mr. Burton's conclusion concerning the use of clasp brakes in order to stop trains in a short distance should be in the mind of every railroad official when the question of new equipment is raised. This is recognized, for in 1915 the Master Car Builders' Association adopted as recommended practice, the rule that all passenger cars with four-wheel trucks weighing 96,000 lb. and over, and all passenger cars with six-wheel trucks weighing 1[illegible]6,000 lb. and over should be equipped with clasp brakes.

C. H. SMITH[1]. The subject has been so thoroughly covered by the author, who is the "father of clasp brakes," as to leave little either to criticize or add. To the advantages which the author has stated it might be added that the clasp brake has accomplished more successfully that which was previously sought for by the adoption of the brake-slack adjuster, i.e., taking up slack due to shoe wear as well as other lost motion in the brake rigging and trucks. The slack adjuster now becomes a necessary adjunct to the clasp brake and will perform its functions as intended.

Our limited experience with the clasp brake confirms all that the author claims. No new passenger equipment will be constructed without this valuable improvement. Moreover, with its adoption upon important train equipments the way is opened for one of the next desirable improvements in brake mechanisms, i.e., that which will justify producing simultaneous application as well as release of brakes on all cars of the train, which can be done with the electric-control device. The use of the clasp brake on all the cars in an entire train will not completely eliminate possible rough handling because of the time interval between head- and rear-end application.

THE TALBOT BOILER, PAUL A. TALBOT

D. K. WARNER[1]. I should like to ask Mr. Talbot if any experiments have been made since those conducted by the U. S. Geological Survey on the temperature of the tube metal in a boiler of natural gravity circulation. Those tests showed that the tube temperature remained practically that of the water in the tubes. As the capacity for receiving heat depends only on the temperature difference between the tube and the gases, and the velocity of the gases, I would take exception to Mr. Talbot's statement that "the high rate of evaporation is obtained because of the high velocity of water in the tubes." Inasmuch as with ordinary circulation the tubes keep as cool as the water, it would seem that the high capacity of this boiler is due more to the high furnace temperature, the absence of baffles and other special features. I would also like to ask if the periodic temperature variations mentioned would be great enough to injure a turbine.

Because of its freedom of expansion this boiler seems admirably suited for very high capacities. May I ask the author then why he limits himself to a draft of two inches of water. Using 20 lb. of air per lb. of oil, a draft of 24 inches of water requires by theory less than 1½ per cent of the power developed in the turbo-generator. Electric fans are built of 50 per cent efficiency, so that it would actually require but 3 per cent of the power. High capacities will be essential on the new ships of such great power and the flue temperatures can be kept down by adding a few layers of tubes.

A Norwegian shipbuilding concern, according to *The Times Engineering Supplement* (Jan. 26, 1917), is about to construct a reinforced-concrete ship of 3000 tons dead-weight capacity which is to be fitted with Diesel engines for propulsive purposes. Hitherto the use of this material has been restricted to small vessels.

The coefficient of friction of bronze on bronze has been the subject of some recent experiments by the U. S. Reclamation Service. The tests were conducted on the slide-gates at the Pathfinder, Arrowrock, and Elephant Butte dams. The head on the center of the gates varied between 50 ft. and 125 ft. The average coefficient of friction of the opening stroke ranged between 0.31 and 0.42 for the different dams. The maximum ranged between 0.383 and 0.44. The average for the closing stroke ranged between 0.254 and 0.29 and the maximum between 0.268 and 0.34. (*Western Engineering*, vol. 8, no. 2, February 1917, p. 51).

LARGE RECLAMATION PUMPING PLANT

Discussion by Louisiana Engineers of the Details of Design of the Largest Drainage Pumping Plant in California

A JOINT meeting of the Louisiana Society of Members of the American Society of Civil Engineers and of the New Orleans Section of The American Society of Mechanical Engineers, held on October 2, 1916, was devoted to the discussion of a paper entitled The Design and Test of a Large Reclamation Pumping Plant,[1] by G. C. Noble, of San Francisco. This discussion is published below, preceded by a brief abstract of the paper, which is given here for the purpose of reference.

The paper by G. C. Noble, purchasing engineer of the Shell Company of California, entitled The Design and Test of a Large Reclamation Pumping Plant, originally presented at a meeting of the San Francisco Section of The American Society of Mechanical Engineers, published in the May 1916 issue of The Journal and later presented at the Thirty-Seventh Annual Meeting of The Society in December 1916, was also discussed at a joint meeting of the New Orleans local association of the American Society of Civil Engineers and the New Orleans Section of The American Society of Mechanical Engineers on October 2, 1916.

Mr. Noble's paper dealt with drainage problems involved in Reclamation District 1500, one of the largest in the state of California, the solution of which problems resulted in the construction of the largest reclamation plant in this country; and what the New Orleans engineers had to say regarding the California project makes interesting reading. Also, the discussion here presented brings out incidentally a number of valuable points in connection with present drainage practice in Louisiana.

ABSTRACT OF PAPER

During the last few years there has been a very rapid development in reclamation work along the rivers of California, with a decided tendency towards the formation of very large districts. To accomplish true reclamation it is necessary not only to exclude the flood or overflow waters, but also to provide a drainage and pumping system which will insure the removal of all surface water, whether from rainfall or seepage, as fast as it accumulates. Failure to do so will result in a very great loss, and it is therefore imperative that the system be designed in accordance with the best engineering practice.

In this paper the author outlines the problems involved in the case of Reclamation District 1500, commonly called Sutter Basin, one of the largest in the state of California, the solution of which has resulted in the construction of the largest reclamation pumping plant in this country, having six 800-hp. units. The District has an area of about 66,000 acres, and to reclaim the tract it was necessary to surround it with some 70 miles of levees.

The author first describes the methods employed in determining the amount of drainage water due to run-off from rainfall and to seepage through levee banks, to be handled by the pumping plant, and after a study of data dealing with the maximum pumping head, concludes that the plant capacity should consist of pumps that can lift 1000 sec-ft. against a 29-ft. head.

As the plant was accessible to three electric-power companies, it was decided to use motor-driven centrifugal pumps; six units, each a 50-in. pump having a normal capacity of 175 sec-ft. against a discharge head of 29 ft. and driven by an 800-hp. motor, being decided on as offering the most satisfactory arrangement and best economical design. Power is delivered at 2200 volts from three 1500-kva. outdoor-type oil-cooled transformers receiving energy at 60,000 volts.

Inasmuch as the district would be flooded the first year after installing the plant on account of non-completion of the levees, and also as a protection against damage to pumps from flooding due to possible breaking of levee at high water, it was necessary to design the walls of the (reinforced-concrete) pumping-plant building to withstand a depth of water on the outside of 18. ft. above floor level, which resulted in the use of walls 4 ft. 6 in. thick at the base of the floor line. The uplift pressure on the bottom of the building amounted to nearly 5000 tons.

Results of preliminary tests on one unit are embodied in the paper in a chart, which shows a combined motor and pump efficiency of very nearly 60 per cent at a discharge of 165 sec-ft. and 29 ft. head.

MR. OKEY DISCUSSES THE DETERMINATION OF THE PROPER CAPACITY OF A PUMPING PLANT

CHARLES W. OKEY.[1] The determination of the proper capacity of a pumping plant to remove the drainage water from a given district is the most important step in its design, for the main purpose of the drainage district is agriculture and not pumping water. A pumping plant might be correctly designed as to economy and reliability of operation, yet might be too small to give the district adequate drainage. The loss of even a portion of one crop on the district might easily exceed the entire cost of a plant of sufficient capacity to insure drainage at all times. This fact has been recognized in a number of places where drainage is secured by pumping, and the present tendency is towards larger relative capacity. This additional money spent in a pumping plant is looked upon by the owners of the land as an insurance policy against loss by floods. In addition, the greater feeling of security given by a pumping plant much larger than those around it has resulted in a rise in land values in districts served by extra-large pumping plants over those not so well protected.

The method Mr. Noble has used in arriving at the proper capacity of pumping plant looks reasonable, except that his assumption of 25 per cent as the proportion of the rainfall that will run off is apparently too small. The heaviest rainfall

[1] The Journal, May 1916, page 371.

[1] Senior Drainage Engineer, U. S. Dept. of Agriculture, Tulane Univ., New Orleans, La.

comes during the winter season when the evaporation is at a minimum. At similar times the percentage of rainfall appearing as run-off has been as high as 75 or 80 per cent on the districts in Louisiana. The plant capacity as he has designed it is about 0.40 in. per 24 hours. The main drainage channel has a storage capacity slightly over 0.20 in. During the storm period of January 12 to 15, 1911, when 5.16 in. of rain fell, the pumping plant and reservoir canals would have been able to take care of a depth of 1.80 in. over the entire watershed, provided the canals were empty when the rain started. This would have been about 35 per cent of the total rainfall. If the land were saturated when this storm started, from comparison with results in Louisiana, this capacity appears to be rather small. However, most of the studies on the districts in Louisiana have been made on much smaller ones than that mentioned by Mr. Noble. As a result, two, or possibly three, days should be added to the period over which pumping occurred. Assuming as he did that the reservoir canal would be empty on January 13, and would be empty again on January 17, the total amount pumped would be about 2.00 in., or nearly 40 per cent of the total.

Even if it were considered that only 60 per cent of the total rainfall had to be handled in five days, starting on January 13, the capacity of the pump would have had to be 0.60 in. per 24 hours. Looking at the question from the side of the investor or actual cultivator of the land, this additional safeguard might be justified.

Present practice in Louisiana is to install a capacity of about 1.50 in. on districts of about 4000 or 5000 acres, where the reservoir capacity is perhaps 0.50 in. Of course the rainfall is much heavier, but this would provide for a much larger percentage of run-off than provided by Mr. Noble. It is to be hoped that records of operation of this plant will be kept, so that future districts will have some actual data on which to base the design of capacity.

MR. HUTSON DISCUSSES THE DISPOSITION OF DISCHARGE PIPES FOR VARIOUS SUBSOIL CONDITIONS

H. L. HUTSON. We should not, in my opinion, compare this plant, with its high lift, with our local drainage projects. Mr. Noble's problem is more nearly comparable with our irrigation plants of Western Louisiana and Texas than with our low-lift drainage plants of the coast country. It is also similar to the drainage projects of Iowa and Illinois, but with somewhat higher lift.

Whether or not it is the best practice to have the discharge pipes pass through or over the levee is, to my mind, a question to be decided with a full knowledge of the strata beneath the plant. If the plant rests on impervious strata, there is no reason why it should not be set in the levee and the pipes pass through the latter, for with a plant of this size acting as a core wall, there would be no danger of leakage along the pipes, endangering the levee. In fact, the plant itself may act as a dam, just as do most of the city drainage plants in New Orleans, and as in the case of some of the irrigation plants in Texas.

If there is only a thin stratum of porous material beneath the plant, this may be cut off by a tight bulkhead of sheet piling and the plant designed as if on an impervious foundation, but care should be taken that the bulkhead is long enough to prevent flow around the ends.

If the plant rests on a porous foundation, we must then so design that the seepage through the porous material will be so retarded as to preclude any movement of the porous material. This may be accomplished by placing the suction and discharge basins a sufficient distance apart for the friction through the porous material at a safe rate of percolation to equal the maximum head. The cheapest way to connect these suction and discharge basins is usually by metal pipes, and there is an added element of safety by having the pipes go over the levee.

As has been pointed out several times in articles on dams, a perfectly safe dam may be built on sand or other porous material, provided proper coefficients are used in figuring the length of travel for the water through the porous material. Mr. W. G. Bligh has given the following:

$$L = CH$$

where H = head of water or difference in level of water above and below dam

L = length of travel for water while percolating through the porous material.

For very fine sand and silt	$C = 18$
For fine sand	$C = 15$
For coarse sand	$C = 12$
For sand and gravel	$C = 9$
For boulders and gravel	$C = 4$ to 6.

If there is a line of sheet piling or a cut-off wall extending into the porous material, L may be measured along the course which the seepage would take, namely, horizontally through the porous strata until it strikes the obstruction, then down one side and up the other, the water following the surfaces of the solid material.

By this use of sheet piling the horizontal distance between suction and discharge basins may be reduced. An apron of impervious material on the discharge side of the plant may also be used to cut down the length of discharge pipe necessary. A row of sheet piling on the outer edge of this apron is also helpful. On the other hand, there is no advantage in having the intake paved with a watertight pavement over using rip-rap merely to prevent scour. If the pavement were watertight, there would probably be uplift enough to crack the pavement.

MR. DUSENBURY COMMENTS ON THE HIGH NOZZLE VELOCITY OF THE PUMPS

ALLEN T. DUSENBURY.[1] Pump manufacturers have urged that nozzle velocities should not exceed 6 or 8 ft. per sec. The nozzle velocity in Mr. Noble's pump, at 175 cu. ft. per sec. discharge, is about 13 ft. per sec. I wondered why this was so, and why they did not enlarge the nozzles on the pumps.

The paper states little or nothing about the type of soil and its reservoir capacity throughout the district, so that the amount of run-off cannot be judged. If the soil is like some of the Sacramento Valley land, where the peat bogs are 50 ft. thick, then the matter of building levees is a continuous one. If that is the character of soil, it does not require much pumping capacity to handle the water, because the soil will take care of so much with the small rainfalls in the district.

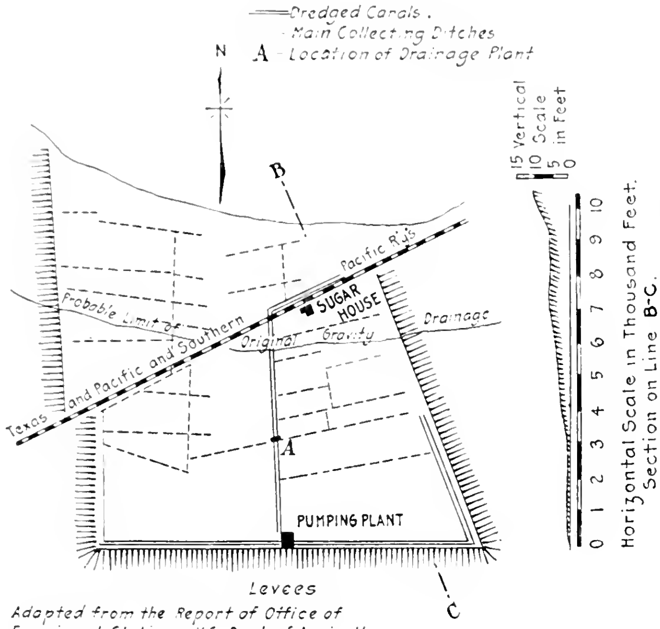
The paper states nothing about the character of the soil under the pumping plant, and does not show how the danger from seepage flow under the plant is overcome. With a difference of head of sometimes 29 ft., there would be a very great tendency for leakage to occur. I presume possibly that, for such high heads, the manufacturers did not advocate the lesser nozzle velocity so much as they do in the low-lift pumps.

[1] Vice-President and Chief Engineer, Louisiana Meadows Co., New Orleans, La.

Mr. Hutson replied to Mr. Dusenbury that the pump manufacturers do change the rating of the pump with the increase of head. He did not know just what was the rule employed, but the higher the head pumped against, the greater capacity would the manufacturers rate their pump at, because a high velocity was necessary in the impeller to pump against that head.

MR. SHAW DESCRIBES DITCHING AND CANAL SYSTEM USED ON A LOUISIANA PLANTATION

A. M. Shaw.[1] In connection with the question raised by Mr. Dusenbury in regard to the soil formation, we know that the Sacramento River is a silt bearing stream. I am not positive with regard to the Feather River, but the contour lines given on the map in the paper would indicate that this river has also built up a set of natural levees along its banks, and for that reason one would feel almost certain that at the confluence of these two rivers, at which point the pumping plant has been constructed, a silt formation rather than a peaty bog would be found, typical of certain other portions of the Sacramento River Valley.



Adapted from the Report of Office of Experiment Stations, U.S. Dept of Agriculture June 30, 1909.

Fig. 1 Willswood Plantation, St. Charles Parish, La., Showing Canals and Main Ditches

A point to be stressed is the division of the tract being reclaimed into zones, with the idea of bringing the water to the pumping plant in such a manner that it can work to best serve the entire area. That is a method of arrangement of ditches which has not been given sufficient attention in this section. It does not enter into the problem, particularly, of the reclamation of the typical flat prairie lands of the Delta country, but does enter very markedly into the reclamation or the drainage of the river-front lands. We have in the vicinity of New Orleans a number of tracts which are drained artificially, which are the result of evolution from the river-front lands. These were drained by gravity, but finding the back lands more fertile, the owners have pushed back their rear levee and gradually taken in additional land. This new land was too low to drain by gravity, so they have put in pumps on the back levee and drained the entire tract artificially, the result being that the original system of ditches is incorporated in the final system; and on account of the original system having been designed with the idea of getting rid of the water as quickly as possible, it usually dumps the water from the front lands (which are more or less impervious and have a considerable slope) back to the pumping plant, a mile or more away, at about the same time that the nearer water reaches the pumps.

The plan of the author was to divide this into zones, so that the supply of water to be pumped out will reach the plant in a manner which will enable it to serve the entire tract as nearly as possible at an equal rate. It is doubtful if any system of ditches could be designed to serve a tract of this nature in an ideal manner under all conditions of rainfall. As the author states, the elevation of the lowest point in the basin is 19 ft. above datum, and the maximum elevation is 30 ft. above datum. Undoubtedly, therefore, a great deal of benefit is derived by designing the ditches as the paper describes.

It occurs to one reading the paper that a tract of the size of the District and a project of such importance would justify at least a consideration of two separate drainage systems. That is something which should be considered in a number of the reclamation projects along the river front in the locality of New Orleans, and which has been worked out already on a very small scale in a few instances. With the data furnished in regard to the project under discussion, it is impossible to judge whether a separate system of drainage would be justified in that particular instance, but it is interesting to note what might be worked out provided things are as we assume.

A gravity drainage system might be installed following approximately the 24-ft. contour (starting a little above that, so as to get fall for the ditch), and diverting all of the water from the area above that contour to some point which would be reasonably near, if not at, a point which would be suitable also for the main pumping plant of the district. If it could be brought to the same point, all the works could be controlled by the same crew of men that would operate the pumping plant. Such a system would not be operative at times of extreme high water in the Sacramento River, but it is reasonable to suppose that a large proportion of the flood water during a considerable portion of the year could be discharged by gravity, or, if not by gravity, by an independent low-lift pump, at a very much lesser cost per acre of drainage than by allowing the entire flood to drop into the sump, making necessary the maximum lift for the entire drainage.

The two points discussed should be given more attention in the Louisiana drainage projects along the Mississippi River, where we have somewhat similar conditions to contend with.

At Willswood we have a situation about as shown in Fig. 1. The entire tract contains about 2500 acres. The original plantation ran a little over one-third of the distance back from the river.

I believe that the original tract was drained entirely by gravity. As the demand for more land was felt, a levee was constructed as shown in the figure, which enclosed a considerably greater area. This new land was too low to drain by gravity and a drainage wheel was constructed. All the drainage from the older as well as from the new lands was brought to this point and pumped out on the prairies to the rear. The

[1] Consulting Engineer, New Orleans, La.

ditching system was on the regular "checkerboard" system common to the front lands, and this system was extended to the entire final project, which was installed fifteen or twenty years ago.

As will be noted, the entire ditching and canal system is of such a design that drainage water will be rushed to the pumps as quickly as practicable from even the most distant points of the plantation. As the land farthest from the pumps is practically impervious and has a slope of from 2 to 4 ft. per 1000 ft., the effect is to flood the lower lands before the water from even ordinarily heavy storms can be removed—this in spite of the fact that the Willswood plantation has an exceptionally large pumping capacity per acre of area served. The damage from such flooding in the past has not been serious, as the rear lands have usually been planted in cane, and cane will stand flooding for several hours, but the arrangement is not ideal.

An element which we find common in the multiple-unit plants in Louisiana, which does not seem to have been taken advantage of in the plant under discussion, is the variation in the type of pumps and power units. These, apparently, are exact duplicates throughout the entire plant. It is probable that in the case at hand, as well as in those that we have in this section, a very large proportion of the pumping could be done by one or two units, and in a project of that size it would seem reasonable to suppose that those one or two units might be designed for a maximum efficiency. The sacrifice of efficiency for financial reasons is considered, and probably wisely so, but in the multiple-unit plants in this section we find that we can put in one pump of a sort of constant-duty type which will handle a great deal of water over a long period of time with greater economy than the pumps which are put in as purely flood-protection equipment.

MR. NELSON DESCRIBES AN ARRANGEMENT OF PUMP AND DISCHARGE PIPE HAVING SEVERAL ADVANTAGES

B. S. NELSON.[1] With reference to the question of bringing the discharge pipes over the levee, Mr. Noble said that there would be considerable trouble in priming the pumps without the gate valves, due to the long line of discharge pipe.

[1] Engineer for A. M. Lockett & Co., Ltd., New Orleans, La.

It might be of interest to show, Fig. 2, a somewhat similar installation near Pharr, Texas, where we had very nearly the same conditions, although the plant in question is an irrigation plant. The pump in this installation is located about 400 ft. away from the concrete bulkhead of the canal. The discharge pipe is a wooden-stave pipe about 7 ft. in diameter. One end of this pipe connects to this concrete bulkhead, the other end runs back to within a short distance of the pump. On the discharge of the pump we used an ordinary sheet iron increaser, with an inexpensive flap valve on the end, to recover the velocity head. This valve was about 5 ft. in diameter

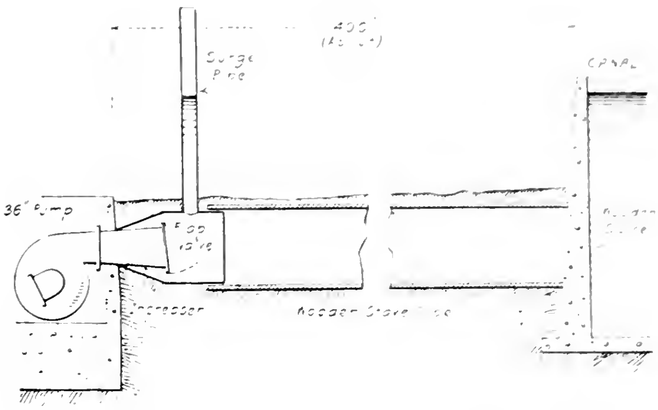


FIG. 2 ARRANGEMENT OF PUMP AND DISCHARGE PIPE USED IN INSTALLATION AT PHARR, TEX.

On the outside of the increaser was riveted a larger cone, one end fastened to the increaser and the other to the wooden pipe.

The advantages of this arrangement were that we recovered the velocity head by using an increaser; we substituted an inexpensive flap valve for an expensive gate valve, and we could prime the pump without priming the long discharge pipe.

There is no trouble about getting at the flap valve, because a sort of wooden sluice gate was arranged which could be let down over the bulkhead end of the wooden pipe and this pipe then drained back through the pump so that workmen could get into it.

CORRESPONDENCE

CONTRIBUTIONS to the Correspondence Department of The Journal by members of The American Society of Mechanical Engineers are solicited by the Publication Committee. Contributions particularly welcomed are suggestions on Society Affairs, discussions of papers published in The Journal, or brief articles of current interest to mechanical engineers.

Underfeed-Stoker Furnace Action

TO THE EDITOR:

In the course of the discussion of Mr. Victor J. Azbe's paper on Power-Plant Efficiency, presented at the recent Annual Meeting of the Society, the statement was made that the process of combustion in an underfeed-stoker furnace is identical with the surface-combustion process. It was claimed that the short flame resulting from this process of firing was due to an accelerated chemical reaction brought about by the combined presence of the combustible gases with air and the solid fuel bed, interacting with surface-combustion effect.

The real reason for the comparatively short flame (especially with our Eastern bituminous coals) from the bed of fuel operated by the underfeed principle is that the combustible gases liberated from the coal are subjected to a blowpipe action during their travel through the upper part of the fuel bed.

Owing to the separated positions of the retorts in the underfeed stoker, the greater part of the distilling-off of the volatile gases occurs only in isolated strips running from front to rear of the furnace and not evenly over the entire area of the fire bed.

Air is required to consume this gas rapidly, and in order to penetrate the part of the fuel bed found above the grate sur-

face and lying above the retorts, where the rapid gas distillation is taking place, the air is blasted into the fire bed through restricted openings or tuyères under more or less pressure; and it will be noted that these air openings, instead of being evenly distributed under the entire bed of fuel, are located in separated longitudinal lines, from front to back of the furnace, underlying only a small percentage of the grate area.

The quantity of air thus delivered is therefore very many times the volume needed to complete the combustion of the fuel located *directly* above the air openings (as the fuel lying over other portions of the grate area must also receive its needed air supply).

This projected air traveling at a considerable velocity is forced through the various cracks and interstices found in the compact fuel bed, which coal has been delivered into the furnace by the ramming action of the feeding plungers (or screws).

We next find this air mixing with the rising and very recently liberated gases, and both air and gases are hurled together against the heated masses of fuel (or coke) which intercept their paths of escape to the combustion chamber above.

Thus we have the blast of cool air meeting the combustible gases (heated in this case to a degree approximately their ignition temperature) and being projected with them against the highly heated baffle (or block) which acts with regenerative effect with just the same conditions and effect that we find in blowpipe practice in our shops or laboratories.

Such handling of the air and gas within the fuel bed tends to support a temperature within the burning mass which raises their mixture above the temperature of ignition of the gas, and this temperature is further maintained by the burning of the coke resulting from the coal after its gas has been distilled off.

The coke, which is, practically speaking, carbon, when raised to temperatures of from 1500 deg. to 1850 deg. fahr. would normally, under a quiescent state, burn to carbon monoxide, but with a large excess of air present which is made to sweep over its surface at high velocity, experiment has shown that carbon dioxide is produced.

These two actions of the gas and air within the fire bed have a tendency to complete the combustion of the combustible matter within the fuel mass, but only at such positions as the air and gas can find sufficiently free paths of passage to travel with sufficient velocity.

Owing to the compressed condition of the fuel bed, due to the ramming action of the feeding devices, the fire bed of the underfeed-stoker furnace is never open and spongy and of equal density over its entire surface, but it loosens up over the grate surface in lumps (especially with the caking coals) and opens in cracks and fissures, through which separated openings the air and newly generated gas are hurried at too high a velocity to produce a thoroughly even burning effect throughout any cross-section of the fuel bed.

It is due to the compactness of the fire bed and the small area of air-admission openings of the underfeed stoker that the (comparatively speaking) high air-blast pressures are required to force sufficient air into the furnace to complete the combustion of the entire fuel.

The underfeed method of stoking unquestionably produces a certain amount of gas combustion within its more or less deep fuel beds and this results in the production of a shorter flame above the fire surface, but does it always go far enough in this direction to eliminate all smoke?

At one time I was called upon to investigate a form of down-draft furnace which the inventor claimed embodied the principle of surface combustion, and I believe that he had a much better right to make such a claim than those trying to apply this theory to the action taking place in the fire beds of underfeed stokers, notwithstanding the fact that I could not wholly support the claim of the down-draft-furnace inventor.

The so-called *surface combustion* is produced by bringing a mixture of combustible gas with but slight excess of its required amount of air into intimate or penetrative contact with some solid body of a more or less porous, open, or granular structure heated to a high temperature, which form of solid body is known as a *catalyzer*. The tendency of the resulting chemical action (or catalytic action) taking place at the surface of these catalytic agents is to increase the velocity of the chemical combination, while the agents, in themselves, are left unchanged at the end of the reaction.

Every heated solid substance exerts some accelerating action on gaseous reactions, notably the metals of the platinum group in some of their subdivided forms, nickel, iron oxide, firebrick or other refractories, but it does not stand to reason that all other solids beside those named are equally effective catalyzers.

Reactions always occur most slowly in free-gas space, but there is the greatest difference in the catalytic activity of the various solids.

Catalytic action may take place on the surface of a lump of glowing coal during the time its occluded or liberated gases are given off by the action of the heat, but it does not follow that lumps of coal brought in contact with other surrounding gas act to very materially accelerate, in a similar manner, their reaction (necessary to effect the final product of combustion).

There are two ways in which the complete combustion of gases takes place. The first is a homogeneous combustion in which the velocity of the chemical change is dependent upon the order of the reaction, and combustion or reactions occur equally throughout the entire mass; in the second a heterogeneous combustion occurs in layers immediately in contact with a hot surface, and for this reason the term *surface combustion* has been given to this form of combustion.

But it must be noted that in order to obtain an effective surface combustion a refractory material is best adapted, and the activity of the surface presented is governed by the texture of the surface, the condition of the surface as related to the kind of gas consumed, and its retarding effect upon the films of gas formed.

Surface combustion is effected by forcing an explosive mixture of air and gas through refractory porous diaphragms, and in such cases the combustion seems to be concentrated within the interstices of the fireclay body, being always the most intense on the outer surface, where no flame is visible.

Surface combustion is also obtained by a somewhat less effective means by which the air and gas are forced through a porous bed of incandescent granular refractory material under pressure, and under favorable conditions the flame disappears and a high temperature results at the surface of the catalyzer.

With a proper understanding of what the term *surface combustion* is intended to convey, there can be but little reason for making a claim that the action in the fuel bed of an underfeed furnace is one of surface combustion.

In the underfeed furnace we find a great number of reverberatory actions taking place throughout the fuel bed, which rapidly raise the temperature of the air and gases; and by thus increasing their temperature we hasten the rate of combustion and this tends to produce a higher temperature, the same as is produced in ordinary blowpipe practice, where the flame is projected against a block having the ability to maintain a

high temperature; but it is not reasonable to call such an action one of surface combustion.

Albert A. Cary.

New York, N. Y.

Systematic Committee Work in Technical Societies

To the Editor:

Referring to the letter on systematic committee work in technical societies, submitted by Mr. Hess, I must take exception to Mr. Hess's strictures on the Research Committee. It is evident that he is imperfectly informed about the Committee's activity and methods, in undertaking a somewhat sweeping criticism. It is true that so far as actual research is concerned the Committee has, until last year, never been able to produce final results. No research can be handled without money. The Committee has been the means of getting some research work done, the results being published in papers. It is certainly very far from true that the Committee is not active. It is also not true that they have not asked for funds. I have upon several occasions applied to the Secretary for funds for the research work, but up to the present none have been allotted. The $300 mentioned by Mr. Hess is intended only for clerical work, and is entirely used up for that purpose.

The report of the Finance Committee to which Mr. Hess refers certainly shows some signs of life on the part of the Committee, so that at least it may be attested as something not quite ornamental. However, as regards the coordination of effort, I am in agreement with Mr. Hess, and the efforts of the Research Committee have been intended to aid in securing it. The writer has several times pointed out the need for eliminating duplicate committees in the various societies with a view to avoiding duplicate work; there should be some general plan adopted for correlating the work of all societies. The latest movement for the accomplishment of this end has been by way of the National Academy of Sciences, but there appears to be no more difficult task than trying to get people together on the subject of research. We have many different research bodies in this country, all more or less endowed, employed upon scattering research. These would produce their results much more efficiently if they were correlated so that no overlapping work was undertaken. It would appear to be the duty of the new secretary of the National Research Council to be the center through whom all of these various research activities would be cleared. I agree with Mr. Hess that the absence of funds is a handicap in getting results, but it is not at all impossible to obtain funds.

With regard to the suggested plan of Mr. Hess, perhaps he is not aware that the Research Committee is already working along these lines, except that the sub-committees have as yet never had any funds allotted to them, but have procured what funds they could from outside sources. There is all the more credit due, I think, in this case to those sub-committees that have accomplished definite results.

R. J. S. Pigott.

Bridgeport, Conn. *Chairman Research Committee.*

WORK OF THE BOILER CODE COMMITTEE

The Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York City.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply, is then prepared by the Committee and passed upon at a regular meeting of the Committee. This interpretation is later submitted to the Council of the Society for approval, after which it is issued to the inquirer and simultaneously published in The Journal, in order that anyone interested may readily secure the latest information concerning the interpretation.

Below are given the interpretations of the Committee as approved by the Council on February 16, 1917, in Cases Nos. 76, 116, and 124 to 135 inclusive. In this report, as previously, the names of inquirers have been omitted.

Case No. 76 (Reopened)

Inquiry: What net area should be considered in calculating staybolts with tell-tale holes drilled in their ends? Also an opinion is requested whether in determining the load on a bolt, the full pitch dimensions of the area stayed should be used, or whether the area occupied by the bolt itself should be deducted.

Reply: The question as to the area of a drilled staybolt is answered by Par. 220, which specifies clearly the net cross sectional area of the stay. The full pitch dimensions of the stays should be employed in determining the total area and the area occupied by the bolt itself may be deducted to determine the net area to be supported by the stays and the load carried by the stays.

Case No. 116

Inquiry: In the case of safety valves does the second sentence of Par. 286 require the raised face specified as a detail in Tables 15 and 16 of the Appendix? Would it not be better practice to make the boiler flanges of all safety valves flat-faced?

Reply: It is the opinion of the Committee that flanged cast iron pipe fittings used for boiler parts, for pressures up to and including 160 lb. per sq. in. shall conform to the American Standards given in Tables 15 and 16 of the Appendix, except that the face of the flange of a safety valve as well as that of a safety valve nozzle, shall be flat and without the raised face. The face of the flange of a safety valve, as well as that of a safety valve nozzle, shall have a flat face for pressures up to and including 250 lb. per sq. in. and shall have a raised face at higher pressures.

Case No. 124

Inquiry: *a* Where reinforcing of heads is provided for as in locomotive type boilers, the heads being braced by separate plates, what material may be used for this reinforcing plate, as well as also for the gusset plates?

b Does Par. 269 allow the use of two safety valves whose combined area is equal to the 3 in. valve?

c Is it allowable under Pars. 182 and 183 to insert a row of staybolts through the center of a joint, the spacing to be the same as the outer row of rivets in the joint?

Reply: a It is the opinion of the Committee that this question is answered by Pars. 2 and 5 of the Boiler Code, flange steel being acceptable where not exposed to the fire or products of combustion.

b The intent of Par. 269 will be expressed by adding the following words to the paragraph: "In which case one or more safety valves may be used."

c A row of staybolts is allowable through the center of a joint provided the requirements in the Code as to back pitch of rivets and dimensions of ligaments are met, by considering a staybolt or other hole in the same way as a rivet hole. Where the plates at the two ends of a stay are of different thicknesses, the pitch must be that corresponding to the thinnest plate.

Case No. 125

Inquiry: Is the method of fastening the crown sheet of the boiler shown in Fig. 6 by using staybolts that pass through

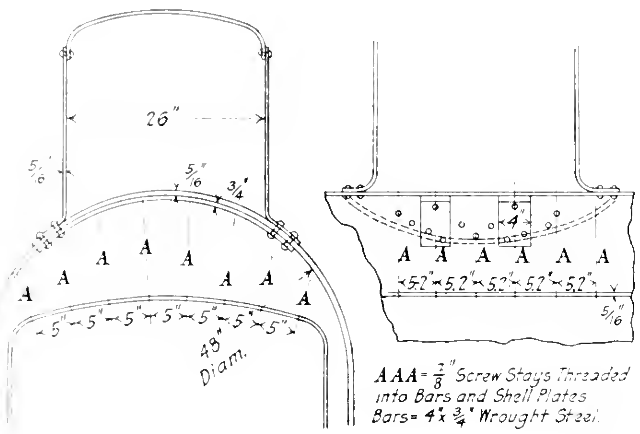

Fig. 6 Proposed Method of Reinforcing Neutral Sheet under Dome for Support of Crown Sheet

the reinforced neutral sheet underneath the dome strong enough to withstand 100 lb. working pressure?

Reply: The construction illustrated is unusual and is not directly covered in the Boiler Code. The stresses in the reinforcing bars which come beneath the dome are similar to those which exist in crown bars and the required section of the bars may be computed by the rules given in Par. 230 of the Code.

Case No. 126 (Annulled)

Case No. 127

Inquiry: An interpretation is requested of Pars. 323, 324, and 325 in their application to different types of boilers. If Par. 325 is to be used in conjunction with Pars. 323 and 324 and refers to return tubular boilers only, should this not be so stated?

Reply: It is the opinion of the Committee that Par. 325 refers to any type of boiler.

Case No. 128

Inquiry: An explanation is desired of the conflict that appears to exist between Pars. 12 and 268 of the Boiler Code in their application to the use of cast iron nozzles for boilers.

Reply: It is the intent of the rules in the Boiler Code not to allow the use of cast iron nozzles riveted to the shell of a steam boiler for any temperature or pressure.

Case No. 129

Inquiry: In view of the difficulty at the present time of securing iron boiler tubes to meet the Code specifications, permission is requested to use wrought iron tubes which on account of their small diameter, cannot meet the flanging test.

Reply: The requirements of the flanging test for wrought iron tubes will be changed in the forthcoming revision of the Code. They will be so modified as to make it possible for acceptable wrought iron tubes of small diameter to meet them.

Case No. 130

Inquiry: A ruling is requested covering the staying of crown sheets of furnaces of locomotive type boilers by means of a special form of arch bars which are attached to the crown sheet by stays spaced at regular intervals.

Reply: There are no rules in the Boiler Code for arch bars of the special type referred to. There are rules given in Par. 230 for straight crown bars and girder stays which would have to be modified in order to apply them to these special arch bars.

Where furnaces require staying Par. 212 of the Code specifies that they shall be stayed as flat surfaces. The rule for staying as flat surfaces is given in Par. 199 and the maximum pitch of staybolts at different working pressures and for different thicknesses of plate is given in Table 3. These rules and the values in the table would apply in the case of the stays used between the top of the furnace and the arch bars, the pitch to be used being the maximum, measured either between the rows of stays in the arch bars or between the stays in a given arch bar. By applying the rules for stays the allowable working pressure can be determined if the crown bars are made strong enough and are properly supported at their ends.

Case No. 131

Inquiry: Will a $1\frac{1}{2}$-in. brass body safety valve be acceptable on the outlet from a superheater provided it conforms to all other requirements of the Boiler Code?

Reply: It is the opinion of the Committee that under Par. 289 the use of brass body safety valves is not permissible with superheated steam.

Case No. 132

Inquiry: Is Par. 321 intended to apply to the fittings on water columns as well as to the pipe connections? In other words can extra heavy cast iron crosses be used for the fittings instead of brass crosses?

Reply: It is the opinion of the Committee that Par. 321 applies to the fittings as well as the pipe connections. Therefore cast iron crosses or other fittings will not be permissible.

Case No. 133 (Annulled)

Case No. 134 (Annulled)

Case No. 135

Inquiry: Is it permissible to make use of patch bolts instead of rivets in fastening the flanged edges of the sheets in a door hole of a locomotive type boiler, where accessibility to the work for riveting is impossible?

Reply: Where there is insufficient room to use rivets such as in the specific case mentioned the Boiler Code does not prohibit the use of patch bolts.

SOCIETY AFFAIRS

A Record of the Current Activities of the Society, its Members, Council, Committees, Sections and Student Branches; and an Account of Professional Affairs of Interest to the Membership

THE most far-reaching step, not only recently but in the progress of the engineering profession, has been taken during the past month. Upon a foundation laid by others, President Hollis, with characteristic energy, has actually accomplished the preliminary work toward the organization of a clearing house for the engineering profession, whereby questions of general interest may be properly considered and a means provided for united action upon matters of concern common to engineers and the public. All societies, participating by representatives, like the states in our Union, preserve in all respects their prerogatives, entities and freedom for individual action. This organization is to be known as the Engineering Council. It will be a department of the United Engineering Society and participated in by not only the Founder Societies of the United Engineering Society but all the other leading societies.

Each of the societies will be represented by one or more delegates according to its size and, unless objection is made by some of the member societies, the Council shall speak for the societies collectively on public questions. When there is objection the matter shall be referred to the governing bodies of the societies whose representatives protested.

The Council will meet in various places and in this way establish a national atmosphere, and in every way develop a representative but nevertheless democratic organization.

In the past month Dr. Hollis has also secured the coöperation of the other societies in a joint telegram to the President of the United States, as follows:

To the President,

Executive Mansion, Washington, D. C.

We, the presidents of the National Societies of Civil, Mining, Mechanical, and Electrical Engineers, and of United Engineering Society, with a membership of thirty thousand, cordially unite in supporting Congress and the Administration in the stand for freedom and safety on the seas, and we are confident that we represent the membership of the four societies in offering to assist toward the organization of engineers for service to our country in case of war.

(Signed) GEORGE H. PEGRAM, President,
American Society of Civil Engineers.
L. D. RICKETTS, President,
American Institute of Mining Engineers.
IRA N. HOLLIS, President,
American Society of Mechanical Engineers.
H. W. BUCK, President,
American Institute of Electrical Engineers.
CHARLES F. RAND, President,
United Engineering Society.

The President of our Society and myself have received a number of communications and oral inquiries in regard to enrollment in an officers' reserve corps, and it is the expectation within the near future to take up comprehensively the whole subject and to prepare a digest of all the acts of Congress and authorizations pertaining to this matter both for the Army and for the Navy, and to instruct the membership in general terms as to how engineers may secure assignment to positions for which they are especially fitted.

CALVIN W. RICE, *Secretary.*

THE SPRING MEETING AT CINCINNATI

PLANS for the Spring Meeting of The American Society of Mechanical Engineers, the semi-annual general meeting of the Society, to be held in Cincinnati, Ohio, May 21 to 24, are sufficiently under way to enable the following announcements regarding the professional and social events of the meeting to be made.

There will be a Joint Session with the Machine Tool Builders' Association, as previously announced in The Journal. A session has been planned by the Sub-Committee on Gas Power on the subject of High-Speed Gasoline Engines. Recent developments in connection with high-speed engines for automobile and aviation service, based on a clearer understanding of the processes of combustion and the mechanical problems involved, have led to increase of mean effective pressure and improvement in combustion-chamber design, valve arrangements, balancing, and the use of aluminum alloys, etc.

There will be a Machine-Shop Session in charge of the Sub-Committee on Machine Shop Practice, at which will be discussed questions relating to the design and construction of machine tools, and other problems of interest, particularly to those engineers connected with the machine-tool industry.

A session on some of the economic principles involved in the manufacture of munitions, such as questions relating to financing, specifications, inspection, design of parts for quantity manufacture, principles of organization which have been found successful, etc., will also be held.

The proposed entertainment features include an informal gathering on the first evening, with addresses of welcome, followed by dancing.

On Tuesday morning there will be a trolley ride to Fort Thomas, a beautiful site overlooking the Ohio River, and of particular interest at this time. During the afternoon the ladies will be invited to visit Rookwood Pottery and the Art Museum. For the evening there is planned a symphony concert or a dinner followed by dancing at the Zoo.

On Wednesday morning a trip will be arranged for the ladies through the leading stores of Cincinnati, some of which are very handsome, and a trip through one of the city's skyscrapers in order to get a view of the city and the Ohio Valley. On Wednesday afternoon a trip will be ar-

ranged to the Zoo in special cars; this is a very beautiful place in May and one of great interest.

On Thursday morning a special ladies' program, the details of which have not yet been arranged, will be given. In the afternoon a motor-car ride is planned to prominent places in Cincinnati, including Mt. Storm Park, University of Cincinnati, Observatory, and Ault Park.

On Friday morning trips will be arranged at additional expense to members to such places as Fort Ancient, Mammoth Cave, in Kentucky, and Lexington, Kentucky. It is believed that cards can be provided for all guests to one of the golf clubs here.

The Society has already held two general meetings at Cincinnati, one in May 1890 and the other in May 1900.

Nothing can furnish a more potent testimony of the growth of the Society than a reperusal of the minutes of the 1890 Cincinnati Meeting. In it we find that "the Council has made arrangements by which the Society will enter upon the occupancy of part of the house No. 12 West Thirty-first Street, New York City." The seating capacity of the auditorium is given as "over two hundred," the top floor and basement were leased to other parties to meet the financial burden imposed during the first year of occupancy of the House. The American Institute of Electrical Engineers were also tenants, etc. Comparison with present facilities of the Society in the Engineering Societies' Building—and the present accommodation is becoming increasingly inadequate—affords sufficient evidence that each of the twenty-six years passed has contributed its share to the general and unmistakable progress of the Society and ipso facto of the Engineer.

The 1890 Cincinnati Meeting is memorable for the report of a "Special Committee appointed by the Council to memorialize the Congress of the United States in the matter of a suitable recognition by the Nation of the work of Capt. John Ericsson, late member of this Society." It will perhaps be recalled that in The Journal for May 1916 are reported the speeches of members representing the Society at the Hearing of the Bill before Congress for the erection of a monument to the memory of Ericsson, which, it is to be hoped, will lead to the speedy consummation of the projected memorial.

The 1900 Cincinnati Meeting was also a memorable one, for on that occasion was read the first paper on motor vehicles, "The Automobile Wagon for Heavy Duty," by Arthur Herschmann. "I believe," said the author in his conclusion, "that if the motor wagon is given an unobstructed field and fair play, it will hold its own and oust the horse-drawn truck in short order. The change must come, and with perhaps the exception of the harness maker, everybody will benefit by it." The investigations described in that paper were made in the interest of the Adams Express Co., and, judging by their ubiquitous delivery wagons alone, have borne ample fruit.

We have every reason therefore to look forward to the third Cincinnati Meeting, and do not doubt that it will be instrumental in furthering the general interests of the Society and the profession.

Cincinnati is a convenient city for conventions, being within a night's ride of the principal cities of the central states and many southern and eastern cities; also within twenty hours of the Atlantic seaboard and the western prairies. It is the terminal for 200,000 miles of first-class railways; to the east there are six trunk lines, the Big Four Division of the New York Central, connecting New York and Boston, the Erie and Pennsylvania from New York, Baltimore and Ohio from New York and Baltimore, Chesapeake and Ohio from New York and Newport News, and the Norfolk and Western from Norfolk, Va. From the west come the trunk lines of the Big Four, and Baltimore and Ohio.

The city has a great many points of interest. There is the Rookwood Pottery, located on the brow of Mt. Adams, overlooking the downtown section of the city. Here the beautiful Rookwood ware is produced; every piece is a separate and distinct creation of the artist and is given a finish by a secret process which has never been successfully imitated. Nothing is more interesting than to watch the potter take a piece of wet clay and before the eyes of the visitor make it into a vase which, after it has been burned in the great furnaces for many days, receives a finishing touch causing it to become a thing of great beauty and high value.

Then there is the Fernbank Dam in the Ohio River at the western city limits, said to be the largest movable dam in the world. It is one of the series of fifty-four locks and dams being built by the United States Government in the Ohio River, at a cost of about sixty million dollars, to make it navigable, with a depth of not less than nine feet, all the way from Pittsburgh to the river's mouth at Cairo.

The Cincinnati University in Burnet Woods comprises McMicken, Cunningham, and Hanna Halls, the Van Wormer Library, Engineering Hall, Chemistry Building, Gymnasium, Power Plant and Observatory, which latter is on Mount Lookout, six miles from the center of the city. It is the only municipal university in the United States. The entire group of buildings cost nearly $2,000,000. The Ohio Mechanics' Institute is another great educational institution. It is now housed in a magnificent new structure at Walnut, Canal and Clay Streets, which accommodates 4000 students, and is a big factor among scientific and industrial training schools. Cincinnati has a city hall which cost $2,000,000, and three new high schools which in architecture and appointments are not excelled in any city in the United States. The government building and custom house on Fifth Avenue cost over $6,000,000. A new municipal hospital cost $4,000,000.

Other points meriting the attention of the visitor are: the water-tower, a stone structure 120 ft. high, surrounded by a beautiful residence district; from the Fort may be had what is said to be the finest river view in the United States. The Tyler Davidson Fountain, given to the city by Henry Probasco as a memorial to Tyler Davidson, a public-spirited citizen of the old days in Cincinnati (this was cast at the Royal Bronze Foundry in Bavaria and is made of old cannon from numerous battlefields of Europe); the Old St. Peter's Cathedral; the hall where Robert G. Ingersoll made his famous "plumed knight" speech in nominating James G. Blaine for President; the inclined planes which lift cars from the downtown levels to the top of the surrounding hills; and the Music Hall on Elm Street, opposite Washington Park.

Cincinnati has a system of public parks and boulevards which covers about 2500 acres, and is now undergoing extensions and improvements. The oldest is Eden Park, located on the crest of Mt. Adams. It was once the vineyard of Nicholas Longworth, great-grandfather of Congressman Longworth. When the late King Edward VII of England visited Cincinnati, while Prince of Wales, he pronounced Eden Park the most beautiful natural park of any he had seen in his travels. Others have testified to the beauty of this park and especially to the splendor of the river scenery. Other beautiful parks in Cincinnati are Burnet Woods, in which is located the University of Cincinnati; Lincoln Park and Washington Park, the latter being located in the downtown district, where thousands tarry for a few minutes each bright day.

Members attending this meeting will have an opportunity of making tours in various directions, besides the parties already arranged, as stated at the beginning. Among the points most easily reached from Cincinnati may be mentioned: Chattanooga, Tenn., where the battlefields of Lookout Mountain, Signal Mountain and Missionary Ridge offer sentiment, history and beauty; Boonesborough, Ky., which is the oldest settlement established by English-speaking people in the Mississippi Valley, and which lies on the west bank of Kentucky River, about 150 miles from Cincinnati. Lincoln's birthplace, near Hodgenville, Ky., is another place of historical interest in Kentucky, easily reached from Cincinnati; Mammoth Cave and Colossal Cavern are 200 miles distant from Cincinnati, being about eight miles from Glasgow Junction, Ky.; the tomb of President Harrison is situated at North Bend, fifteen miles from Cincinnati; Point Pleasant, Ohio, the home and birthplace of Ulysses S. Grant, is only about twenty miles from Cincinnati, while Georgetown, where the great General spent his boyhood, is but forty miles distant.

Cincinnati has quite a German element in its population and its view of life has been much influenced by the German idea of hard work when work is on the program and wholesome recreation when there is time to play. Back of it all there is a people whose hospitality has always been of the most open-hearted kind, a people ready to give the Society a hearty welcome at its forthcoming meeting there.

Nominations for Officers of the Am. Soc. M. E.

For Election in December 1917

The Constitution of the Society in C 47 provides among the Annual Committees:

"A Nominating Committee appointed by the President."

It further provides in C 48

A "Special Nominating Committee: Twenty or more persons entitled to vote may constitute themselves a Special Nominating Committee, with the same powers as the Annual Nominating Committee."

The procedure in the nominations for office is provided in the following By-Laws:

B-27 A Nominating Committee of five members, not members of the Council, shall be appointed before February first of each year by the President. The Secretary shall publish the names of this Committee in the March issue of The Journal together with a request to the voting membership of the Society that they recommend to the Committee the names of eligible persons for the elective offices to be filled at the next election. This Committee shall deliver to the Secretary in writing between the first and the fifteenth of June the names of its nominees for the various effective offices next falling vacant under the Constitution, together with the written consent of each nominee. The names of the nominees for the various offices proposed by this Committee shall be published by the Secretary under the names of the Committee in the July issue of The Journal.

B-28 A special Nominating Committee, if organized, shall on or before October fifteenth, present to the Secretary the names of its nominees for the elective offices next falling vacant under the Constitution, together with the written consent of each nominee. The names of the nominees for the various offices proposed by this Committee shall be published by the Secretary under the names of this Committee in the November issue of The Journal.

There are to be elected in December next:

A President to hold office for one year

Three Vice-Presidents to hold office for two years

Three Managers to hold office for three years

A Treasurer to hold office for one year

The President, Ira N. Hollis, has appointed the following Nominating Committee for these officers:

Willis H. Carrier, of Buffalo

Fredk. W. Gay, of San Francisco

A. M. Lockett, of New Orleans

Paul B. Morgan, of Worcester

Louis E. Strothman, of Milwaukee

These names were selected by the following Sections, grouped geographically, and accepted by the President:

Group 1 San Francisco and Los Angeles

Group 2 Atlanta, Birmingham, Cincinnati, New Orleans and St. Louis

Group 3 Chicago, Detroit, Indianapolis, Milwaukee and Minnesota

Group 4 Boston, New Haven and Worcester

Group 5 Baltimore, Buffalo, Erie, New York and Philadelphia

This Nominating Committee is to meet at the Spring Meeting of the Society in Cincinnati, Ohio, May 21-24, and would be pleased to receive suggestions from the membership.

Under the terms of By-Laws B-27 and B-28 the voting membership are requested to send the Nominating Committee or Committees, in care of the Secretary, 29 West 39th Street, New York, N. Y., their recommendations of names for any or all of the elective offices to be filled at the next election.

These recommendations should be sent in early and not later than June 1st.

Sir William H. White Memorial

It will be remembered that shortly after the death of Sir William White, on Feb. 27, 1913, a movement was initiated to establish a suitable memorial in his honor.

The members of many engineering and scientific societies of several nations were given an opportunity to subscribe and a committee of notable engineers was formed in England to take charge of the movement.

A considerable number of the members of The American Society of Mechanical Engineers responded to the invitation and a goodly sum was sent to the committee in the name of our Society, of which Sir William was an Honorary Member.

The work has been consummated and the Committee has made its final report.

The memorial funds, resulting from private subscription, amounted to over \$16,000.

The memorial has taken three forms:

1 The "Sir William White Research Scholarship in Naval Architecture," which is to be administered by the Council of the Institution of Naval Architects with a fund of nearly \$14,000.

2 A donation to Westminster Hospital of \$500.

3 A portrait panel in marble of Sir William erected in the Entrance Hall of the Institution of Civil Engineers in London, in which about \$1500 is invested.

A reproduction of this latter memorial is shown in this number of The Journal.

A larger reproduction will be suitably inscribed and framed and placed on the wall of the Society's home.

Thus has been accomplished the desire of many engineers of many nations to do honor to an engineer of great distinction and a man of most lovely character.

The Committee of the Am.Soc.M.E. was Jesse M. Smith, *chairman;* Alexander C. Humphreys, Frederick R. Hutton.

The Americanization Movement

The Chamber of Commerce of the United States, whose Immigration Committee is displaying special activities in the direction of absorbing foreign elements into our national stock, is to be congratulated on its recent efforts to enlist the coöperation of the engineering profession in the furtherance of Americanization. A dinner was given on January 19, followed by a discussion on The Engineer in Americanization, in which quite a number of speakers took part.

Portrait Panel of Sir William Henry White

Dr. Hollis, President Am.Soc.M.E., touching on the question under discussion, said that the underlying aspect of the European War related to the attitude of the individual toward government: whether he believed in the government and heart and soul obeyed the orders of a government, or whether the government was a mere machine through which the individual was permitted to develop as high as possible in the service of mankind. He could not help feel that this was the most important side of preparedness in this country, and that too much emphasis had been put on *military* at the expense of *service* to our nation. He had never believed that the foreigners in this country, Russian, German, English, French or any other, were against America, nor that we have any German population opposed to American institutions.

He favored some definite constructive suggestion rather than discussion, and thought the best thing to do with regard to foreigners coming to America was to organize for after-work education and scholarships, and a general education, especially in American institutions. In conclusion he said he felt very strongly that the Engineer would back up anything the Chamber of Commerce might propose towards the betterment of citizenship in America and of Americanization.

Mr. Howard E. Coffin spoke on the constitution of the Committee on Industrial Preparedness, and the work it had already accomplished in connection with the industrial inventory of the country, the data of which will form the basis of the whole structure toward our national military and naval defence.

With regard to Americanization, he favored employment cards in every employment agency, which would give particulars as to naturalization, when first papers were taken out, etc., followed in due course by a definite declaration that no employee will be raised to a position of responsibility or trust unless he is an American citizen.

Transactions Errata

From time to time the attention of the Society has been called to slight errata in the volumes of Transactions, and these errata have been kept on file and will be compiled and published at an early date.

Mr. F. W. Dean furnishes the following corrected Table 1 of his paper on Damages for Loss of Water Power, which was presented at the December, 1915, meeting of the Society and published in Volume 36 of the Transactions:

TABLE 1 GENERAL COSTS OF POWER BY STEAM AND WATER

Annual Costs of Power by a Steam Plant.	Annual Costs of Power by Water Combined with Steam Sufficient for a Uniform Power	
	Water Power Plant	Auxiliary Steam Plant
Interest	Interest	Interest
Depreciation	Depreciation	Depreciation
Repairs	Repairs	Repairs
Insurance	Insurance	Insurance
Taxes	Taxes	Taxes
Attendance	Attendance	Attendance
Fuel	....	Fuel
Supplies	Supplies	Supplies

Naval Consulting Board

A special meeting of the Naval Consulting Board of the United States, called at the request of Secretary of the Navy Daniels, was recently held in the Engineering Societies Building for the purpose of considering certain matters which are vital to the proper defense of the United States in the event of war.

William L. Saunders, vice-chairman of the board, presided, and some of the matters discussed were the production and organization of the industries whose outputs would be national necessities in the event of war, aeronautics, transportation,

submarines, mines and torpedoes, and ordnance and explosives.

Among those at the meeting were Bion J. Arnold, Frank J. Sprague, Peter Cooper Hewitt, Howard E. Coffin, Hudson Maxim, Elmer A. Sperry, and Lawrence Addicks, who are members of the board, and Rear Admiral G. E. Burd, Industrial Manager of the New York Navy Yard; Captain W. S. Smith, U. S. N., representing the Navy Department in Washington, and Lieutenant Commander Charles S. McWhorter, one of the submarine experts of the service.

It was voted to notify the Secretary of the Navy that the "board holds itself at the service of the Department of War or of the National Council of Defense, to act as a board of inventions, or in any other capacity which may be of use to the Government in the present emergency."

The board adjourned to meet at the call of the President, who is Thomas A. Edison, who was reelected. William L. Saunders, Peter Cooper Hewitt, and Thomas Robins [illegible] other executive officers elected.

Ericsson Monument

The advisory committee, to be known as the John Ericsson Monument Commission, appointed by the United States Government to handle certain details with regard to the erection and unveiling of the monument to Captain John Ericsson at Washington, includes the following members of The American Society of Mechanical Engineers: John E. Ericsson, Chicago, Ill.; John G. Bergquist, Glenhead, L. I.; F. O. Hoagland, Hartford, Conn.; C. von Philp, Bethlehem, Pa.; Erik Oberg, New York City.

The commission will meet in the spring in Chicago.

CANDIDATES FOR MEMBERSHIP

TO BE VOTED ON AFTER APRIL 10, 1917

The American Society of Mechanical Engineers is an organization for mutual service of over 7700 engineers and associates coöperating with engineers. The membership of the Society comprises Honorary Members, Members, Associates, Associate-Members and Juniors, all elected by ballot of the Council. Application for membership is made on a regular form furnished by the Secretary which provides for a statement of the standing and professional experience of the applicant and requires references from voting members personally acquainted with the applicant. The requirements for admission to the various grades will be furnished upon request.

Below is the list of candidates who have filed applications for membership since the date of the last issue of The Journal. These are classified according to the grades for which their ages quality, and not with regard to professional qualifications, i.e., the ages of those under the first heading place them under either Member, Associate or Associate-Member, those in the next class under Associate-Member or Junior, and those in the third class under Junior grade only. Applications for change of grading are also posted.

The Membership Committee, and in turn the Council, urge the members to scrutinize this list with care and advise the Secretary promptly of any objections to the candidates posted. All correspondence in this regard is strictly confidential. Unless objection is made to any of the candidates by April 10, 1917, and providing satisfactory replies have been received from the required number of references, they will be balloted upon by the Council. Those elected will be notified about May 20.

NEW APPLICATIONS

FOR CONSIDERATION AS MEMBER, ASSOCIATE OR ASSOCIATE-MEMBER

Alabama

GABOURY, John D., Superintendent of Power, Woodward Iron Co., Woodward
LANDGREBE, Karl L., Assistant General Superintendent, Tenn. Coal, Iron & R. R. Co., Ensley
LIND, Edward W., Draftsman, Tenn. Coal, Iron & R. R. Co., Fairfield
LOWE, James R., Vice-Pres., McCleary Jemison Mchy. Co., Ensley
MAHONEY, John C., Turbine Engineer, Atlanta Dist., General Electric Co., Atlanta
MOFFETT, Charles A., Vice-President, Gulf States Steel Co., Birmingham
TAYLOR, Flemen C., General Gas Foreman, Tenn. Coal, Iron & R. R. Co., Ensley
WILCOX, William F., Superintendent Water Supply, Tenn. Coal, Iron & R. R. Co., Ensley

California

ALLEN, Arthur P., Chief Draftsman, Engineering Department, Union Iron Works Co., San Francisco
BENNETT, Frederick, formerly manager of Mchy. Dept., Parrott & Co., San Francisco
DEMAREST, D. C., Manager, Angels Iron Works, Angels Camp
FIELD, Robert N., Mechanical Engineer, Mammoth Copper Mining Co., Kennett
KIBELE, O. B., General Superintendent Transportation, Union Co., Los Angeles
SCHARPENBERG, Charles C., Efficiency Engineer, Standard Oil Co., Bakersfield
STODDARD, Charles H., Engineer, Moore & Scott Iron Works, San Francisco

Colorado

CARSON, Louis T., Assistant Chief Engineer, Great Western Sugar Co., Denver
DEWEY, Louis C., Mechanical Engineer, Jackson Compressor Co., Denver
JONES, Arthur L., District Engineer, General Electric Co., Denver

Connecticut

ABBOTT, Roy J., Section Leader, Pratt & Whitney Co., [illegible]
ALLGRUNN, Frederick S., Mechanical [illegible], Remington Arms & Ammunition Co., [illegible]
FRAY, George H., Assistant to Me[illegible], Bridgeport Brass Co., [illegible]
GORDON, William A., General [illegible], Birmingham Iron Fdy., [illegible]
HULME, Percy A., Assistant [illegible], New Britain Mch. Co., [illegible]
JOHNSON, Eugene A., Eq[illegible], Remington Arms U[illegible] M[illegible], [illegible]
LATTIN, Albert N., Me[illegible], New Departure Mfg. Co., [illegible]
LOOMER, Lewis L., Testing [illegible], American Brass Co., [illegible]
McGRATH, William C., Sup[illegible], Stamford Rolling Mills Co., [illegible]
MUNSON, John G., Construction [illegible], J. G. White Engineering Corp., New Haven
OTTERSON, John E., Vice-President, Winchester Repeating Arms Co., New Haven
PICKLES, John F., With W. F. Pickles, Manufacturing Automatic Drying Regulator for Paper Making Machines, Buckland
RODNEY, Keith R., Engineering, Bullard Machine Tool Co., Bridgeport

ROMER, ALBERT J., Sales Engineer,
The New Departure Mfg. Co., Bristol

SIMPSON, GEORGE P., Superintendent,
Oven Equipment & Mfg. Co., New Haven

UNGER, G. A., Technical Manager and Chief Engineer,
S K F Ball Bearing Co., Hartford

WILLIAMS, CHARLES E., General Manager,
William L. Gilbert Clock Co., Winsted

Delaware

BRENTLINGER, JOHN M., Operative Engineering Div., Engineering Department,
E. I. du Pont de Nemours & Co., Wilmington

DERR, RALPH, Engineer, Mech. Experimental Div.,
E. I. du Pont de Nemours & Co., Wilmington

FOSTER, WILLIAM B., Assistant Chief Engineer,
E. I. duPont de Nemours & Co., Wilmington

MEREDITH, HARRY P., Master Mech., Maryland & Delaware Div.,
Baltimore & Washington R. R., Wilmington

SCHULZ, LOU E., Construction Engineer,
E. I. du Pont de Nemours & Co., Wilmington

SELLERS, WILLIAM F., President,
Edge Moor Iron Co., Edge Moor

STONE, ROY L., Operative Engineer,
E. I. du Pont de Nemours & Co., Wilmington

WARNER, JACOB L., Assistant Engineer,
E. I. du Pont de Nemours & Co., Wilmington

District of Columbia

JOHNSON, ELMER, Assistant Mechanical Engineer,
U. S. Office of Public Roads & Rural Engrg., Washington

SMITH, THOMAS W., Mechanical Engineer, Transportation Div.,
Quartermaster Corps, U. S. Army, Washington

Georgia

GREAGAN, JOHN J., Sales Engineer,
Allis Chalmers Mfg. Co., of Wis., Atlanta

Illinois

AKERS, AXEL, Engineer in Charge Mech. Section,
Department of Public Works, Bureau of Engineering, Chicago

ALLAN, CHARLES D., Consulting Engineer, Chicago

BABCOCK, FRED R., Proprietor,
Electrical & Power Equipment Co., Chicago

CROSBY, WILLIAM F., Service Manager,
International Motor Co., Chicago

HANNIFIN, A. V., Treasurer and Works Engineer,
Hannifin Mfg. Co., Chicago

HENLEY, ROY A., General Superintendent,
The American Cement Plaster Co., Chicago

HENNING, CHARLES F., Manager,
Gypsum Fireproofing Co., Chicago

KYLE, SAMUEL C., Consulting Engineer,
Engineering & Sales Corp., Chicago

MONTAGUE, EDWARD, Superintendent,
Amalgamated Mchy. Corp., Chicago

SEIDLE, NORMAN R., Manager Plate Construction Dept.,
Joseph T. Ryerson & Son, Chicago

WILDER, THOMAS E., President,
Wilder & Co., Chicago

WILSON, GEORGE L., Counsel Service,
Efficiency Engineering Lines, Chicago

Indiana

EVANS, BERNARD C., Die Designing,
General Electric Co., Fort Wayne

HAYDON, GEORGE F., Chief Engineer,
Prudential Casualty Co., Indianapolis

WILLIAMS, LEWIS M., Sales Engineer,
Fort Wayne Oil & Supply Co., Fort Wayne

Kentucky

TREFZ, JULIUS J., General Superintendent,
The Anglo-American Mill Co., Owensboro

Louisiana

ANDERSON, JAMES, JR., Superintendent, Pipe Line Dept.,
Standard Oil Co. of La., Shreveport

SPENCER, ORRIE G., Chief and Consulting Engineer,
Lyon Lumber Co., Garyville

Maine

GOLDSMITH, WILLIAM H., JR., Chief Draftsman,
Biddeford Plant, Saco-Lowell Shops, Biddeford

SAWYER, HARRY B., Treasurer,
The Kelley Spear Co., Bath

Maryland

BRIDGES, JOHN S., President and General Manager,
Coale Muffler & Safety Valve Co., Baltimore

SCHMEISSER, ERNEST G., Secretary and Treasurer,
Baltimore Oil Engine Co., Baltimore

WYGODSKY, LEON, Vice-President and General Manager,
Baltimore Oil Engine Co., Baltimore

Massachusetts

CURRY, MALCOLM, General Engineer,
American Thread Co., Holyoke

LOFTUS, JAMES J., Sales Engineer,
Reed Prentice Co., Worcester

MACKAY, SIMON, Works Manager,
The L. S. Starrett Co., Athol

NEWTON, ALBERT E.,
With Reed Prentice Co., Worcester

NORTH, FRED K., Superintendent,
American Steam Gauge & Valve Mfg. Co., Boston

ROBINSON, CHARLES A., Mechanical Superintendent,
Merrimack Mfg. Co., Lowell

SOPER, CLEVELAND C., Instructor Machine Drawing and Design,
Wentworth Institute, Boston

TENNEY, Arthur A., Purchasing Agent,
Fitchburg Steam Engine Co., Fitchburg

WARREN, RALPH L., General Manager,
Warren Brothers Co., Boston

WIDDERBERG, OSCAR A., Machine and Mill Designer,
American Steel & Wire Co., Worcester

Michigan

DE VISSER, JOHN H., Treasurer,
The Coon-De Visser Co., Detroit

HEAVENRICH, OSMOND D., Chief Engineer,
Detroit Pressed Steel Co., Detroit

KNUDSON, WILLIAM S., Mechanical Engineer,
Ford Motor Co., Detroit

PARKS, BURRITT A., Consulting Engineer,
Byron E. Parks & Son, Grand Rapids

RIX, MILTON H., General Superintendent,
Sheffield Car Co., Three Rivers

TOWER, GLENN L., Mechanical Engineering,
With The Detroit Edison Co., Detroit

Minnesota

LILYGREEN, FRANK G., General Shop Superintendent,
American Hoist & Derrick Co., St. Paul

MOYER, MALCOLM B., President,
Moyer Manufacturing Co., Montevideo

Missouri

ROSENOW, HENRY F., Chief Engineer Power Plants,
Brown Shoe Co., St. Louis

STOLBERG, EMIL C., Assistant Engineer, Improvement Dept.,
American Car & Foundry Co., St. Louis

Nebraska

SOUTH, JOHN H., Superintendent,
Nebraska Culvert & Mfg. Co., Wahoo

New Jersey

CARNEY, EDWARD B., Mechanical Engineer,
Safety Insulated Wire & Cable Co., Bayonne

CAVE, HENRY, Director Technical Research,
Davis-Bournonville Co., Jersey City

HANNUM, JOHN P., Mechanical Assistant Superintendent,
E. I. du Pont de Nemours & Co., Carney's Point

LOVEKIN, LUTHER D., Engineer,
New York Shipbuilding Co., Camden

ROUSE, RICHARD, JR., Manager Manufacturing Dept.,
Boynton Furnace Co., Jersey City

VAIL, THOMAS C., Superintendent,
Spicer Mfg. Co., South Plainfield

WELDON, JOHN M., Power Engineer,
E. I. du Pont de Nemours Co., Carney Point

New York

ALLEN, OLIVER F., Power and Mining Department,
General Electric Co., New York

AYR, SAMUEL, Factory Manager,
Automatic Transportation Co., Buffalo

BENSEL, JOHN A., Consulting Engineer, New York

BUSSEY, CHARLES C., President,
Coal Products Corporation of America, New York

COLDWELL, ARTHUR J., Superintendent,
Coldwell Lawn Mower Co., Newburgh

COLE, FORREST W., Mechanical Engineer,
The Solvay Process Co., Syracuse

COLEMAN, CHARLES P., Vice-President,
Worthington Pump & Mchy. Corp., New York

DECKER, RUDOLPH J., M. E.,
Kaolin Prod. Corp., New York

DEVINE, JOSEPH P., President,
J. P. Devine Co., Buffalo

DRAKE, WARREN C., Mechanical Engineer,
Westinghouse Elec. & Mfg. Co., New York

DYGERT, CHARLES B., Equipment Engineer,
Remington Arms U. M. C. Co., Ilion

EVERETT, CHESTER M., Member of Firm,
Hazen, Whipple & Fuller, Cons. Civil Engrs., New York

GOODSPEED, CHARLES A., Machine Tool Salesman, Henry Prentiss Co., New York
GREIST, ALVA O., Consulting Engineer, New York
HAYDEN, THOMAS J., Instructor, Practical and Applied Electricity, Department of Education, New York
HEQUEMBOURG, WALTER J., Assistant General Manager, New York Dock Co., Brooklyn
HIRSCHBERG, CHARLES A., Advertising Manager, Ingersoll-Rand Co., New York
HUDSON, ALBERT H., General Purchasing Agent, Wright-Martin Aircraft Corp., New York
INGLES, ROBERT N., Chief Engineer, M. W. Kellogg Co., New York
ISKOLS, ANATOL D., Mechanical Designer, Switchboard Dept., General Electric Co., Schenectady
JOHNSTON, ROBERT B., Supervisor of General Machining, Remington Arms & Ammunition Co., Ilion
KING, NORMAN M., Engineer in charge, The Singer Building Power Plant, New York
LINDENKOHL, HENRY, Engineer of Construction, American Locomotive Co., Schenectady
McCLEARY, WILLIAM, Superintendent, New York & Richmond Gas Co., New York
MYERS, CHARLES T., Production Engineer, Savage Arms Co., Utica
PECK, ROSS S., Engineer, Westinghouse, Church, Kerr & Co., New York
PEEBLES, ERFORD J., Factory Engineer, Divine Brothers Co., Utica
SACCHI, GUSTAVO A., Engineer, Power Div., Westinghouse Elec. & Mfg. Co., New York
SHAW, HUBERT A., Metallurgist, American Can Co., Geneva
SITNEY, MASSEY, Mechanical Engineer, New York Navy Yard, New York
STALEY, FREDERICK W., Fuel Engineer, The Texas Co., New York
STEWART, JAMES T., Resident Inspector, The Hartford Steam Boiler Inspection & Insurance Co., Utica
TAYLOR, JAMES D., Advisory and Operating Engineer, New York
TUCKER, JOSEPH H., Construction Superintendent, Grant Contracting Co., New York
WILFERT, GEORGE, Assistant Chief Inspector, Remington Arms Union Metallic Cartridge Co., Ilion
WORTH, B. G., Vice-President, Walter Kidde & Co., Inc., New York
WRIGHT, DONALD C., Production Supervisor, Remington U. M. C. Co., Ilion

Ohio

AICHBERGER, CARL, Mechanical Engineer, The Sandusky Foundry & Machine Co., Sandusky
BICKFORD, FRANK, Engineer, The Recording & Computing Mchs. Co., Dayton
BLANCHARD, CHARLES M., Chief Engineer, The Standard Fuel Oil Engine Co., Willoughby
BURGER, FREDERICK W., Superintendent, Delphos Mfg. Co., Delphos
CARMAN, EDWIN S., Secretary and Chief Engineer, The Osborn Mfg. Co., Cleveland
CASE, GEORGE S., Factory Manager, The Lamson & Sessions Co., Cleveland
FULTON, WILLIAM B., Supervising Engineer, The Colin Gardner Paper Co., Middletown
FRYER, WILLIAM H., Chief Engineer, The National Cash Register Co., Dayton
GEOGHEGAN, JOHN T., Mechanical Engineer, C. N. O. & T. P. Rwy., Cincinnati
GIBBONS, MICHAEL J., JR., Secretary, M. J. Gibbons Supply Co., Dayton
LOHMANN, ALFRED P., Engineer in Charge, Engineering Dept., The B. F. Goodrich Co., Akron
MOORE, CHARLES C., Chief Engineer Power Sta., The National Cash Register Co., Dayton
MUELLER, OSCAR W., President, The Mueller Machine Tool Co., Cincinnati
PERKINS, J. B., President, The Hill Clutch Co., Cleveland
PATTERSON, A. HUGO, Contracting Engineer, The Mt. Vernon Bridge Co., Mt. Vernon
PELTZ, ARTHUR C., General Manager, The Morris Machine Tool Co., Cincinnati
RASTALL, WALTER H., Engineer, Worthington Pump & Machinery Corp., Cincinnati
RICHARDS, ARTHUR, Consulting Engineer, Richards Engineering Co., Columbus
ROLLMAN, BRUCE B., Experimental Engineer, New Idea Spreader Co., Coldwater
SAFBERG, B. F., Superintendent, Barberton Works, The Babcock & Wilcox Co., Barberton

TOMPKINS, Harold D., Engineer,
Smooth-On Mfg. Co., Jersey City

WHITE, J. W. Huyler, First Assistant Chief Engineer,
The American Sugar Refining Co., Jersey City

New York

EVANS, Herbert W., District Manager,
Reeves Pulley Co., of Columbus, Ind., New York

FINKEL, J. J., Inspection Engineer,
New England Westinghouse Co., New York

FRAYNE, William D., Sales Engineer,
Ridgway Dynamo & Engine Co., New York

GEARY, Robert J., Engineering Department,
Semet-Solvay Co., Syracuse

GOALWIN, Harry A., Student at Columbia University and occasional work for Moses, Pope & Messer, Cons. Engrs., New York

GOLDRICH, Phillip, Draftsman,
Guarantee Construction Co., New York

GOODSELL, Charles D., Master Mechanic,
Columbian Rope Co., Auburn

HATCH, Frederick N., Engineer,
Westinghouse, Church, Kerr & Co., New York

MORSE, Albert W., Vice-President,
The Anthony Co., Long Island City

NELSON, Charles R., Assistant to Supt. of Manufacture,
Ice Manufacturing Co., New York

POTTER, Ebford M., Supervising Engineer,
Douglas Robinson, Charles S. Brown Co., New York

RYAN, William F., Construction Superintendent,
Interborough Rapid Transit Co., New York

SKINNER, Howard A., Cadet,
Westchester Lighting Co., Gas Department, Mount Vernon

SONDERMAN, Herman C.,
With Brooklyn Rapid Transit System, Brooklyn

STUBER, Adolph, Efficiency Engineer, Camera Works,
Eastman Kodak Co., Rochester

THOMPSON, Dwinel B., Mechanical Inspector,
New York Central R.R., New York

TORNBERG, Isidor, Designer,
R. Hoe & Co., New York

VANDE MARK, Eugene S., Manager Technical Department,
National Employment Exchange, New York

WAHL, James H., Machinery Inspector,
Transit Development Co., Brooklyn

WORTHEN, Charles B., Chief Inspector, Aeroplanes and Aeromotors, Signal Corps., United States Army, College Point

Ohio

BRODERICK, George H., Factory Manager,
Corrugated Container Corp., Columbus

McLAUGHLIN, Glenn D., Maintenance Engineer,
Recording & Computing Machines Co., Dayton

MORNINGSTAR, B. Franklin, Engineer Main Power Station,
The River Furnace Co., Cleveland

SCHIRMER, Carl E., Chief Draftsman,
Schaffer Engineering & Equipment Co., Tiffin

TAGGART, Arthur B., Secretary,
Advance Machinery Co., Toledo

WIGHT, Harry C., Superintendent Div. of Water,
Dayton Water Works, Dayton

Pennsylvania

BENNY, Irwin H., Superintendent Mfg.,
Penn Barrel Co., Philadelphia

BRYANS, Henry B., Engineer Schuylkill District,
Counties Gas & Elec. Co., Norristown

CHURCHILL, Harold W., Executive Engineer, Motor Drill Dept.,
Burke Electric Co., Erie

DOWELL, Henry L., Instructor in Mech. Engrg.,
University of Penn., Philadelphia

HORTON, Ernest J., Mechanical Engineer,
Ruud Manufacturing Co., Pittsburgh

MacLEAN, Archibald, Jr., Marine Engineering Dept.,
Westinghouse Machine Co., East Pittsburgh

ORR, Harold S., Assistant to Superintendent of Inspection,
Remington Arms Co., Eddystone

SCHULZ, Gustav E., Factory Organizer, Instructor of Scientific Management,
Tabor Mfg. Co., Philadelphia

SLAYMAKER, William W., Assistant Mechanical Engineer,
Bureau of Surveys, Philadelphia

South Carolina

LE TELLIER, Louis S., Professor,
The Citadel, The Military College of South Carolina, Charleston

Texas

GUNTHER, Ernest, Sheet Metal Mfg.,
H. Welsh Co., El Paso

Virginia

WILLIAMS, Samuel S., Chief Engineer of Power Stations,
Roanoke Rwy. & Elec. Co., Roanoke

West Virginia

BALLARD, A. M., Chief Engineer,
Wayland Oil & Gas Co., Charleston

Wisconsin

WEGNER, Arnold A., Engineer, Elevating & Conveying Dept.,
Chain Belt Co., Milwaukee

Canada

SMOCK, Harold E., Chief Draftsman,
Page-Hersey Iron Tube & Lead Co., Welland

FOR CONSIDERATION AS JUNIOR

Alabama

GLIMM, William F, Jr., Engineer,
Barrett Co., Fairfield

SPEARMAN, Guy M., Draftsman,
American Cast Iron Pipe Co., Birmingham

Colorado

ROUSE, John E.,
With The United Oil Co., Florence

Connecticut

CLARK, Russell G., Draftsman,
The American Thread Co., Willimantic

HILL, CLARK B.,
with Terry Steam Turbine Co., Hartford

HIRSCH, ROBERT R., Technical Writer, Advertising Dept.,
S. K. F. Ball Bearing Co., Hartford

HOLMS, TURY B., Designing Draftsman,
Terry Steam Turbine Co., Hartford

JOY, JOSEPH, Mechanical Engineer,
Peter A. Frasse & Co., Hartford

LEES, KENNETH F., Chief Engineer,
Greist Mfg. Co., New Haven

MAGZOCCO, DANTE V., Assistant Floor Foreman,
Ashcroft Mfg. Co., Bridgeport

Delaware

TAYLOR, HENRY M., JR.,
with Harlan & Hollingsworth Corp., Wilmington

WISE, ALLEN S., Drafting,
Remington Arms Co., Wilmington

Illinois

EDE, ALBERT B., Engineer,
Cobden Machine Works, Cobden

FLIEGNER, CARL G., Section Chief, Manufacturing Layouts Dept.,
Western Elec. Co., Inc., Cicero

KNIESE, HAROLD G., Engineer,
Central Illinois Light Co., Peoria

Louisiana

HATFIELD, EDWARD R., Draftsman,
Slidell Shipbuilding Co., Slidell

Maryland

WEST, G. ALVIN, Draftsman-Designer,
P. B. & W. R. R. Co., Wilmington

Massachusetts

EDWARDS, HAROLD H., Engineer,
Swift & Co., Boston

GFROERER, HERBERT G., Mechanical Engineer,
Carver Cotton Gin Co., E. Bridgewater

IRWIN, KILSHAW M., Engineer, Station Betterment Dept.,
Stone & Webster Engrg. Corp., Boston

WESTERVELT, NELSON H.,
with Norton Co., Worcester

New Jersey

CLARKSON, ROBERT C., JR., Construction Engineer,
J. E. Campbell Co., Camden

EVANS, JAMES M., Efficiency Engineer,
Hyatt Roller Bearing Co., Harrison

HALAMA, FREDERICK D. H., Draftsman,
Babcock & Wilcox Co., Bayonne

MANDEL, ARTHUR C.,
with Simplex Automobile Co., New Brunswick

SCHLITZ, BERNARD P., Chief Tool Designer,
Simplex Automobile Co., New Brunswick

TALBOT, JOHN A., Superintendent Butler Factory,
Bloomingdale Rubber Co., Bloomingdale

New York

CASABLANCA, FRANK J., Chief Draftsman, Marine Dept.,
Kerr Turbine Co., Wellsville

GAISER, J. H., Secretary,
Booth Felt Co., Inc., Brooklyn

GODSON, JOHN A., Draftsman, Williamsburg Power Station,
Brooklyn Rapid Transit Co., Brooklyn

GREENE, GEORGE F., Draftsman,
M. H. Treadwell Co., New York

HASELTON, PHILIP H., Assistant Manager,
Newman Clock Co., New York

KELLY, WILLIAM, Assistant in M. E. Dept.
Rensselaer Polytechnic Institute, Troy

MAGILL, FRANKLIN R., Engineer, Charge Reduction Gears Design,
Kerr Turbine Co., Wellsville

MARTIN, EDWARD, Efficiency Engineering,
American La France Engine Co., Elmira

MOZEEN, HERBERT D.,
with Mulliner-Enlund Tool Co., Syracuse

QUACKENBUSH, EUGENE S., Engineer,
Friedmann, Robertson & Keeler, New York

SIPE, CHARLES A., Time Study Work,
Remington Typewriter Co., Syracuse

TREWIN, FRANK H., Lubricating Engineer,
Vacuum Oil Co., New York

WALKER, GEORGE G.,
with Vacuum Oil Co., New York

WEBER, HUGH H., Sales Engineer,
The Texas Co., New York

North Carolina

SANDERS, WALTER C., Mechanical Draftsman,
Atlantic Coast Line R. R. Co., Wilmington

Ohio

BRETT, ROY C., Instructor in Mechanical Engineering,
Case School of Applied Science, Cleveland

GALLUP, ALDEN W., Mechanical Engineer,
The Hinde & Dauch Paper Co., Sandusky

MITCHELL, MIRON A.,
with The National Vacuum Machinery Co., Dayton

TERRIBERRY, G. GILSON, Production Engineer,
Niles-Bement Pond Co., Hamilton

WARD, J. CARLTON, JR., Mechanical Engineer,
Niles-Bement Pond Co., Hamilton

Oklahoma

LICHTY, LESTER C., Assistant Professor Mechanical Engrg.,
University of Oklahoma, Norman

Pennsylvania

AICHER, ALFRED L., Chief Draftsman,
F. J. Stokes Machine Co., Philadelphia

DISMUKES, ALBERT R., Efficiency Engineer,
The Emerson Co., Pittsburgh

GANTS, ELWYN T., Assistant Test Engineer,
Pittsburgh Crucible Steel Co., Midland

GIBSON, JULIAN B., Special Apprentice,
Niles-Bement Pond Co., Philadelphia

GRING, WILBUR D., Superintendent Motive Power,
Newport & Shermans Valley R. R. Co., Newport

HENDERSON, DOUGLAS, Instructor, Mechanical Engineering,
The Drexel Institute, Philadelphia

MABREY, NELSON L., Assistant Engineer,
Standard Car Construction Co., Sharon

POWELL, WILLIAM W., Assistant Sales Manager,
Mesta Machine Co., Pittsburgh

SANDER, MALVIN G. F.,
With National Tube Co., Pittsburgh

STROUD, WILLIAM T., Mechanical Engineer,
The Atlantic Refining Co., Philadelphia

Rhode Island

McDEVITT, JOHN N., Vice-President and Assistant Treasurer,
Dover-McDevitt Co., Providence

MANDEVILLE, THEODORE C., Mechanical and Construction, Engrg.,
Sayles Finishing Plants, Saylesville

Texas

CAPEN, FREDERICK B., Mechanical Engineer,
The Texas Co., Port Arthur

EDGAR, OSMER N., Engineer-in-Charge Industrial Dept.,
Houston Chamber of Commerce, Houston

Wisconsin

COVELL, CLIFFORD C., Assistant Draftsman, Car Dept.,
Chicago, St. Paul, Minneapolis & Omaha Ry., Hudson

LAABS, ERIC H., Mechanical Engineer,
Cutler-Hammer Mfg. Co., Milwaukee

LEWIS, DEMPSTER C., Student Apprentice,
Allis-Chalmers Mfg. Co., Milwaukee

WHYTE, TESSEL S., Secretary,
Macomber & Whyte Rope Co., Kenosha

APPLICATIONS FOR CHANGE OF GRADING

PROMOTION FROM ASSOCIATE

Ohio

GRIESS, JUSTIN, Second Vice-President,
The McMyler Interstate Co., Bedford

PROMOTION FROM ASSOCIATE-MEMBER

Georgia

EAGER, WILLIAM G., Second Vice-President,
Valdosta Lighting Co., Valdosta

Massachusetts

GRUNWELL, PAUL C., Mechanical Engineer,
New Bedford Westinghouse Co., Springfield

New York

KETCHUM, SAMUEL, Mechanical Engineer,
M. H. Treadwell Co., New York

PAUSIN, HUGO R., Superintendent Torpedo Dept.,
E. W. Bliss Co., Brooklyn

PROMOTION FROM JUNIOR

Connecticut

TREDWELL, KENNETH L., Production Engineer's Staff,
Winchester Repeating Arms Co., New Haven

Illinois

DOWSON, HARRY R., Experimental Engineer,
F. W. Matthiessen, La Salle

Michigan

IDDLES, ALFRED, Instructor Eng. Division, Michigan Agricultural College, East Lansing

Minnesota

FULLER, FLOYD M., Consulting Mechanical and Electrical Engr., Duluth

STAUDE, EDWIN G., Pres., E. G. Staude Mfg. Co., St. Paul

New York

FARRELL, MORGAN G., Vice President, Willard Case & Co., New York

LIBBEY, RICHARD H., Engineer, Otis Elevator Co., New York

SHOUDY, WILLIAM A., Assistant Mechanical Engineer, J. G. White Engineering Corp., New York

Pennsylvania

MEHARG, LAURENCE, Assistant to Superintendent of Power, Hazel Atlas Glass Co., Washington

West Virginia

MORGAN, JOHN T., District Sales Agent, The Ohio Brass Co., Charlestown

NECROLOGY

J. LINWOOD BROWN

J. Linwood Brown was born in England in 1846. His experience as an engineer began in railway service, in which he progressed to responsible work in mechanical and construction engineering. He built and operated the Southern and West Wisconsin Railroad; held the position of Engineer of Construction with the Mexican Central, the Veronej and Rosstoff Railroad and the Panama Railroad, and was subsequently Superintendent of Motive Power and Maintenance of the Ohio Southern and Pittsburg & Western Railroads. His later work was as Superintendent of the Bureau of Water Supply and Distribution of the city of Allegheny, Pa. He died September 11, 1916. His membership in the Society dates from 1902.

EDWARD THOMAS HENDEE

Edward Thomas Hendee, who was born at Claremont, N. H., February 22, 1880, died at Minneapolis, Minn., November 12, 1916. Upon graduation from New York University in 1900, he received the degree of B.S., and immediately assumed the duties of instructor and assistant professor of chemical and mechanical engineering at New York University, receiving the degrees of M.E. and M.S. during that time. In 1901 he also received the degree of Sc.D. at Columbia University.

In 1902 he associated himself with the firm of Joseph T. Ryerson & Son, Chicago, Ill., as mechanical engineer, and in 1906 became manager of the machinery department. Between the years 1909 and 1913 he acted in the capacity of assistant to the president of the company and in 1913 became secretary, continuing so until his death. Under Mr. Hendee's management both the domestic and foreign machine business and the railway-supply business of the company were very widely extended.

Besides his affiliation with Joseph T. Ryerson & Son, Mr. Hendee was vice-president and director of the Lennox Machine Co. and director of the American Glyco Metal Co. He was a member of the University Club, of the Alumni Board of Trustees of New York University, and of a number of athletic clubs in Chicago. In 1908 he was elected an Associate of this Society and in 1915 became a Member.

WILLIAM KNOX MILLHOLLAND

William Knox Millholland, president of the W. K. Millholland Co., Indianapolis, Ind., and for many years distinguished as a machine-tool designer, died October 9, 1916. He was born in Baltimore, Md., in 1856 and educated in the public schools. In 1874 he started his mechanical training as apprentice with Flynn & Emerick, of Baltimore, Md., in their drafting room and machine department. He remained in their employ five years, during which time he completed an evening course in the Maryland School of Arts and Design. In 1881 he became superintendent of the Falls Rivet and Machine Co., Cuyahoga Falls, O., where he designed and built special machine tools and brought out several inventions. In 1887 he moved to Chicago, Ill., and entered the employ of the M. C. Bullock Mfg. Co., as tool maker and designer. He continued with this company until 1893, when he became superintendent for the Geo. D. Whitcomb Co., designing and building coal-cutting machinery, knitting machinery, etc. In 1898 he became sales manager for the Gisholt Machine Co., Madison, Wis., in which work he continued until 1906, when he organized the International Machine Tool Co., Indianapolis, Ind., and became its secretary. In 1909 he established and became president of the W. K. Millholland Machine Co., in which he was actively interested until the time of his death. Four of his seven sons are continuing the business.

Mr. Millholland was among the first members of the Society, being elected in 1883.

FRANK L. STRONG

Frank L. Strong, who was born in Amherst, Mass., in 1845, was educated in the public schools of Andover, Mass., and later in Phillips Academy. After leaving school, he decided to become a machinist and accordingly apprenticed himself to the Davis & Furber Machine Shop, at North Andover Depot, where he remained two years. During the Civil War he resigned to enlist, and worked his way to third assistant engineer in the Navy, receiving his honorable discharge at its close. He returned to Chicago in 1867 and finally settled there, having been in charge of various large manufacturing plants before he became superintendent and part owner of the Hercules Refrigerating and Ice Machinery Co.

In June, 1898, at the outbreak of the Spanish-American War, he again enlisted as engineer, this time becoming chief engineer of the Illinois Naval Reserves. He returned to Chicago in 1899, entering the field of consulting mechanical engineering, and in 1900 was retained by the Quartermaster-General of the Army as consulting engineer and superintendent of erection of the refrigerating and ice-making plant at Manila. When this work was completed, he opened an office for himself under the name of the Frank L. Strong Machinery Co. (1902) and engaged in private practice, also representing a number of home manufacturers.

Besides being a Member of the Society, to which he was elected in 1912, he was a member of the Business Men's Association in Manila, a member of the Loyal Legion, the Sons of the American Revolution and a number of local clubs in Manila. He was a prominent worker in the Masonic Order, and was Master of the first lodge in Manila.

AMONG THE SECTIONS

AT the recent conference of Sections' delegates a committee was appointed to draft a report embodying suggestions as to activities which may be properly undertaken by the Sections of the Society. Messrs. Hans R. Setz, Chairman of the St. Louis Section, and William G. Starkweather, Secretary of the Boston Section, prepared the report which was adopted by the conference. It contains so many suggestions of value that the Committee on Sections have recommended its reproduction in full. The report follows:

SUGGESTIONS REGARDING LOCAL SECTION ACTIVITIES

Irrespective of local conditions there are certain points which may well be generalized as applying to all the Section meetings. The two principal ones are that the meeting shall attract as large an attendance as possible, and that each member shall leave each meeting with the feeling that the hours devoted to it were well spent.

In these days of engineering and trade journals and excellent technical books, it hardly seems possible to attain the above ends by the presentation of lectures or discussions on highly technical subjects. Exceptions, of course, occur where for instance some new or very important development in connection with local industries is taking place. Generally speaking, however, such papers seldom interest more than just those who are closely connected with the particular subject, which could hardly be otherwise since we have to accept the condition which calls for specialization in our professional work.

The important thing then is to find the subject for our meetings on other fields than the strictly technical, and of such there is indeed a great number. We are all aware of the fact that individually, and especially as a professional unit, engineers are finding practically no recognition in the community, and it is quite certain that this condition will continue to exist as long as we are satisfied to let all our interest be centered on the study and pursuance of our professional work. It is here we see the principal mission of our Sections at the present time and for some time to come.

This brings us at once face to face with the question of speakers, and we believe there is no better way of manifesting and cultivating the spirit of interest and coöperation in the happenings of the community than by securing local speakers. In every town where the existence of a local section of mechanical engineers is warranted, there is enough industrial activity to bring forth problems in which the human side is of predominating importance. Such problems are the question of unemployment, insurance against accidents and disability from old age, education and recreation of workmen and their children, supply of food and commodities, hygienic problems, etc., which are all brought about by the concentration of comparatively great masses of people on small areas, in other words, by the industries for which we engineers are responsible. Much work along such lines has already been done by liberal church societies and philanthropic organizations, although very much lacking in concerted and harmonious effort to bring about a maximum of good. There should be no difficulty to procure speakers on the above subjects who are familiar with the particular local conditions. Securing local speakers on such problems will probably at first not look very attractive, but as such a plan is carried on, the increasing knowledge of the human side of our work is bound to awaken an interest and produce results which cannot fail to be ultimately of the utmost importance to our profession.

Another series of meetings may be arranged to cover questions that will eventually lead to standardization in the determination of cost of manufactured articles. This will become of utmost importance in trying to clearly understand and arrive at a fair method of establishing tariff rates, in which it is to be hoped engineers may have a word to say.

Many other similar questions of local as well as national importance could be cited here which will all help to broaden the interest of engineers and put them on an equal footing with doctors and lawyers who, on account of the strong human element in their professional work, are today exerting such a strong influence in the activities of the community.

The routine of meetings must be adjusted to local requirements, for which no general rules can be laid down.

In the general plan of the meetings there are many who believe a luncheon very desirable either before or after the meeting; this promotes acquaintance, assists in securing pleasant remembrances, helps membership and provides diversion. A supper preceding the meeting seems preferable, since this helps to bring the members together promptly and permits an early closing. This supper need only be of the simplest kind, and in the arrangements it would seem desirable to provide individual tables seating not more than from four to six people.

In deciding on the number of meetings per year, it seems preferable to have a few well-attended interesting affairs rather than frequent forced evenings. Invitations to these meetings are preferably sent out by return postal cards which should reach the members not less than three days, and preferably about seven days, ahead of the meeting.

Where there are no other engineering societies in the community, the mailing list for invitations to the meetings of the local section should include every man in any way actively interested in manufacturing, consulting or directing of industries. Where other engineering societies exist, these mailing lists must, of course, be arranged so as not to interfere with the activities of these sister societies. Frequent revisions of these mailing lists should be made so as to keep them up to date; the names of visitors who are too persistent in availing themselves of our hospitality without response to occasional gentle hints to join the Society should be removed from the list after one year.

In conducting the meetings, papers should start early, say 7:30 or 7:45 p. m.; the time allotted for the presentation of a paper should not exceed three-quarters of an hour. It is advisable to notify those most interested in the subject of the evening that they may be called upon to participate in the discussion; this should be done sufficiently in advance to enable them to prepare themselves. This will lead to a short, snappy session which can be closed early and will leave a good impression.

Particular attention should be paid to the publicity of local Sections' activities. Advance notice should be sent the newspapers, reporters invited, and abstracts furnished, if desired, by the secretary. Publicity for the engineer has long been neglected and is partly to blame for the lack of coöperation in, and disorganized condition of the profession.

Respectfully submitted,

WM. J. STARKWEATHER,
HANS R. SETZ.

BIRMINGHAM, JANUARY 24

The Birmingham Section met on the evening of January 24 when J. T. Anthony, a combustion expert of New York, gave an illustrated lecture on The Locomotive Firebox and Combustion Chamber.

The author considered that future operating conditions of railroads are problematical but the indications are that in addition to present demands for high-hauling capacity there will be a demand for higher speeds. The controlling factor will then be the firebox and its ability to burn the coal properly and liberate the heat required over long periods of time. He presented arguments regarding the effect of heat radiation from the fuel bed, flameways and brick work and the necessity of large firebox volume and long flameway. He showed a number of illustrations of furnace layouts of locomotives in actual operation and the results obtained in fuel economy, boiler capacity and cost of maintenance.

PAUL WRIGHT,
Section Secretary.

BALTIMORE, FEBRUARY 9

Harrington Emerson, Mem.Am.Soc.M.E., of New York, addressed the Baltimore Section at their meeting on February 9, on The Flow of Values Through an Industrial Plant. He

emphasized the fact that the important factors in an organization are the men connected with it. This consideration led Mr. Emerson to study the means of analyzing men before taking them into his organization and he developed a system of character analysis. A series of examples of the application of this method was shown by means of lantern slides.

Turning next to the organization itself, Mr. Emerson threw a diagram on the screen which illustrated in an exceptionally clear manner how values entered the business in the form of cash, from the sale of its securities and finished products, and how this money appeared as values throughout the process until the goods finally reached the customers. The diagram also illustrated the relative potential values of each step in the process, and the functions of the organization and the accounting department were very forcibly brought out by the stop-cocks and returns on the diagram. Mr. Emerson further compared the former view of accounting that simply insisted on authority, allotment and accuracy, and the modern view that demanded real facts regarding production. An interesting discussion followed.

A. G. Christie,
Section Secretary.

BUFFALO, JANUARY 31

Non-Ferrous Metallurgy was the subject of W. M. Corse's paper read before The Engineering Society of Buffalo at their meeting on January 31. Mr. Corse dwelt particularly upon the separate types of brass and bronze when alloyed with phosphorus, manganese, aluminum and silicon. Slides illustrated many of the findings presented in his paper and proved the rapid advances made in non-ferrous metallurgy.

There was a general discussion of Mr. Corse's paper, following which A. L. Johnson briefly explained the activities of the American Society for Testing Materials.

The Engineering Society of Buffalo, which is an outgrowth of the Buffalo Section of the Am.Soc.M.E., held a meeting on February 15, at which the formation of a General Technical Society was discussed. The project includes provision for all branches of the engineering profession, chemists, electro-chemists, etc. Preceding this discussion, Henry A. Brown gave a brief description of The Design of the Latest Development of Milling Cutter, illustrated by slides, showing the attainments of the tool in actual operation.

Louis J. Foley,
Assistant to Secretary.

BOSTON, FEBRUARY 7

More than 500 engineers attended the annual banquet at the Boston City Club on the evening of February 7, representing The American Society of Mechanical Engineers, the American Institute of Electrical Engineers and the Boston Society of Civil Engineers. They unanimously pledged their support to President Wilson in the present crisis and formally voted to send a copy of the following resolution, presented by Dr. Ira N. Hollis, Pres., Am. Soc.M.E., to President Wilson:

> "In view of the grave crisis which our country is facing, and in recognition of the stand recently taken by the President of the United States for the protection of American rights and American lives on the sea.
>
> "BE IT RESOLVED that we, the members of the Convention of the Societies of Electrical, Civil and Mechanical Engineers, held jointly in Boston, Wednesday, February 7, 1917, *first* do pledge ourselves to the support of the President and Congress in their hope that our rights may be maintained by peaceful means, and, *second*, we pledge ourselves likewise to the utmost of our powers and our service, in case our country is forced into war as the only means of maintaining all our rights, freedom and safety the world over.
>
> "BE IT FURTHER RESOLVED that a copy of this resolution be sent to the President at the White House at Washington and to every Senator and Representative from New England."

Dr. Hollis in his subsequent speech declared: "We engineers can take only one attitude, it is that every citizen is permitted, even expected, to develop himself to the highest degree of service for his nation and mankind. There is only one way to do this, and it is for us to unite in the kind of goodwill and good-fellowship that will enable us to work together towards the glory of our country in peace, we hope, but in war if it is absolutely necessary."

Other speakers of the evening were Prof. Elihu Thomson, who stated in part: "We want a definite program laid out by intelligent men, by engineers, and followed without delay. What we need in this country is recognition of the fact that we are in an engineering age, that encouragement of research in scientific matters cannot be carried to excess. Our Government should be willing to spend large sums in putting forward the sciences and their applications." Dr. Hugh Cabot, chief of the Harvard Surgical Unit, who related some of his experiences at the front; Mr. Richard A. Hale, President of the Boston Society of Civil Engineers, who laid stress upon the importance of the engineers' work in case the country should be brought into the war and strongly advocated a central conference of all engineers to fix and distribute their services; and E. W. Ewartz, who spoke on Submarines and illustrated his subject throughout with many interesting slides.

W. G. Starkweather,
Section Secretary.

CHICAGO, JANUARY 19

Col. Henry A. Allen, Consulting Engineer, Garbage Disposal Plant, City of Chicago, gave an illustrated lecture on Problems in Waste Disposal before the Chicago Section at their meeting on January 19. He based his remarks on the information obtained in his study of Chicago's $7,000,000 project. He gave a description of the important disposal systems and told of the new plant being constructed for the city, together with what by-products may be obtained from the plant. By means of stereopticon views he showed the methods of construction and interesting details in apparatus and equipment used in the plant.

Robert E. Thayer,
Section Secretary.

CINCINNATI, JANUARY 18

At a joint meeting of the Cincinnati Section and the Engineers' Club of Cincinnati on January 18, J. H. Hunt, Research Engineer for the Dayton Engineering Laboratories Co., gave an interesting paper on Modern Internal-Combustion-Engine Ignition. The paper considered the requirements of the two general types of electrical ignition: the so-called wipe-spark and the jump-spark ignition. The point was emphasized that the condenser is merely a part of the breaker mechanism and has no useful purpose other than that of enabling the latter to act properly.

Oscillograph records were shown of the oscillation occurring in the primary circuit at the break when the secondary is disconnected, of the primary current and the voltage of the primary coil during normal operation together with the secondary current, and of the reduction in the final value of the current caused by chatter. Records were also shown of apparatus operated at speeds equivalent to 4000 r.p.m. of the engine, the spark obtained with the magneto at low speed, and the prolonged flame or arc persisting after the first spark in the magneto runs at very high speed.

The oscillograms illustrated some of the interesting relations in magneto design which are not generally known.

The paper concluded with a discussion of the effect of ignition upon power, and in this connection it was shown that the only thing ignition can do is to ignite, and that when properly timed any absolutely certain ignition will give all the power the motor is capable of developing at a given speed and carburetor adjustment.

John T. Faig,
Section Secretary.

CINCINNATI, FEBRUARY 15

The February meeting of the Cincinnati Section was held jointly with the Engineers' Club on February 15. A. Lewis Jenkins, Mem.Am.Soc.M.E., Associate Professor of Mechanical Engineering at the University of Cincinnati, read an interesting paper on Combined Stresses. Abner Doble, of the General Electric Co., Detroit, Mich., followed Professor Jenkins with a paper on the Doble Steam Car, of which he is the inventor and which is a new development. This car uses kerosene as fuel, has a water-

tube boiler and uniflow engine. Stereopticon slides illustrated its many novel and interesting features.

John T. Faig,
Section Secretary.

ERIE, FEBRUARY 13

At the meeting of the Engineers Society of Northwestern Pennsylvania, held February 13, to which the members of the Erie Section of the Am.Soc.M.E. were invited, a resolution was passed to affiliate with the Erie Section, to work for the better interests of both societies and of the engineering profession.

The Erie Section will hold a big meeting before the summer recess.

J. P. Wadsworth,
Section Secretary.

LOS ANGELES, JANUARY 24

The Los Angeles Section met on January 24 to discuss How Cities in the United States Are Disposing of Their Sewage. The speakers of the evening were T. D. Allin, Commissioner for the city of Pasadena, and R. V. Orbison, City Engineer of Pasadena. Both Mr. Allin and Mr. Orbison took an extended trip through the United States for the purpose of investigating this subject and their remarks were founded on personal observations.

Ford W. Harris,
Section Secretary.

MINNESOTA, JANUARY 25

On January 25, the Minnesota Section and the American Institute of Electrical Engineers held a joint meeting at the University of Minnesota. The early part of the evening was devoted to a discussion by Charles L. Pillsbury, Mem.Am.Soc.M.E., on What is Valuation. Mr. Pillbsury has just recently perfected for the United States Government a complete physical valuation of all the public utilities within the jurisdiction of the district of Columbia. E. H. Smith followed Mr. Pillsbury with a talk on Oxy-Acetylene Welding and Cutting, illustrating it throughout with practical demonstrations. General discussion followed each of these subjects.

D. M. Forfar,
Section Secretary.

NEW ORLEANS, JANUARY 22

Oil Fuel was the subject of the main paper, presented at the January 22 meeting of the New Orleans Section by B. S. Nelson, Mem.Am.Soc.M.E. Written and verbal discussions by a number of engineers followed.

H. L. Hutson,
Section Secretary.

PHILADELPHIA, FEBRUARY 1

The Philadelphia Section and The Franklin Institute held a joint meeting February 1, when the By-Product Coking Industry was discussed by C. J. Ramsberg, vice-president of the H. Koppers Co., Pittsburgh, Pa. He treated of the design, construction and operation of the modern by-product plant, coal used in by-product coking, coke structures as affected by coal, conditions affecting the efficiency of operation and recovery, and the future of the industry, illustrating his lecture throughout by means of slides and moving pictures. Special attention was devoted to benzol and benzol recovery.

John P. Mudd,
Section Correspondent.

NEW YORK, FEBRUARY 13

The New York Section was well represented at the February 13 meeting when Dr. Ira N. Hollis, Pres.Am.Soc.M.E., discussed The Engineer and Organization, and C. W. Hunt, Mem.Am.Soc.M.E., read a paper on Narrow Gauge Motor Cars.

Following the lines of his well-received addresses before some of the other Sections, Dr. Hollis drew a picture of the progress of mankind as dependent in a very large degree upon engineering. "Engineering," he said, "by eliminating drudgery, has done much for the betterment of humanity." He concluded his remarks with a plea that engineers through their organization, take a more active part in public affairs and announced a plan for closer coöperation between the national engineering societies in matters of common interest.

Mr. Hunt's paper reviewed the growing field for narrow gage motor cars, the several designs intended to meet certain conditions of service, trucks, transmission and loading, and the most economical sizes of car to employ. He also touched upon cable railways and gave data for the solution of problems connected therewith.

A. D. Blake,
Section Secretary.

PROVIDENCE, JANUARY 24

Some Mechanical Analogies in Electricity was the subject of Prof. William S. Franklin's talk before the Providence Engineering Society at their meeting on January 24. By means of some very ingenious mechanical pieces, he illustrated the analogies between mass and inductance, elasticity and capacity, and the effects of these characteristics on both mechanical and electrical systems. He pointed out that there were between twenty and thirty mathematical equations applying to mechanics which take exactly the same form when applied to electricity. President Faunce of Brown University followed Professor Franklin with an expression of gratification at the coöperation of the members of the engineering profession of Rhode Island and Brown University.

Albert E. Thornley,
Corresponding Secretary.

ST. LOUIS, JANUARY 31

On January 31, the St. Louis Section and the Associated Engineering Societies of St. Louis held a joint meeting, when George R. Wadleigh, Mem.Am.Soc.M.E., read a paper on Cotton-Mill Design. He described the processes involved in the manufacture of plain unbleached cotton goods and the major features of cotton-mill design. At the conclusion of the paper there was general discussion by the members of the Section.

Good-will and jollity reigned at the Annual Dinner of the Engineering Club of St. Louis and the Associated Engineering Societies, held at the City Club on January 24.

L. A. Day,
Section Secretary.

ST. LOUIS, FEBRUARY 10

Louis C. Nordmeyer, Mem.Am.Soc.M.E., of the firm of Tait & Nordmeyer Engineering Co., gave a lecture with illustrations on China at the meeting of the St. Louis Section on February 10. Mr. Nordmeyer related some of his interesting experiences while engaged in important engineering work in Shanghai.

On February 14 the Associated Engineering Societies of St. Louis held a joint meeting with the American Society of Engineering Contractors, when Mr. Alroy S. Phillips, Attorney, spoke on The Workmen's Compensation Law. Mr. Phillips was chairman of the legislative committee appointed under former Governor Hadley of St. Louis to investigate workmen's compensation laws throughout the country.

L. A. Day,
Section Secretary.

STUDENT BRANCHES

The large group of Student Branches was augmented by the Council at its meeting on February 16 by the approval of petitions received from the engineering students at Johns Hopkins University, the University of Pittsburgh, and Washington University. This brings the total number of Student Branches up to forty-three.

Plans for a Joint Meeting of Student-Branch members are being perfected. This meeting will occur on Friday afternoon and evening, March 30, at the Engineering Societies

Building, 29 West 39th Street, New York. In addition to the four Metropolitan Student Branches (Columbia University, New York University, Polytechnic Institute of Brooklyn and Stevens Institute of Technology) who have charge of the arrangements, it is expected that the Student Members at Pennsylvania State College and Yale University will also participate. Other Student Branches are urged to arrange to participate and individual student members and graduate student members will also be welcome.

BUCKNELL UNIVERSITY

At the meeting of the Bucknell University Student Branch on February 5, H. C. Liebensberger gave a very comprehensive talk on The Manufacture of Coke in Southern Virginia. He described the methods employed in taking coal from the mine, giving his hearers an insight into the various operations in coal handling before it is finally taken from the beehive ovens and loaded on cars. Professors Kepple and Burpee, Mem.Am.Soc.M.E., took part in the discussion which followed.

On February 7, Professor Burpee gave an instructive illustrated lecture before the students on The Combustion of Fuel, and Heat Transmission with Special Reference to Steam Boilers.

C. M. KRINER,
Branch Secretary.

COLORADO STATE AGRICULTURAL COLLEGE

The meeting of the Student Branch of the State Agricultural College on January 15 was devoted to an inspection of the new heating plant of the college. Prof. L. D. Crain, Mem.Am.Soc.M.E., discussed in detail the workings of the plant. He called attention to the two Stirling boilers, each of 234 hp. and equipped with automatic stokers, the steel bunkers with capacity of 250 tons, the pumps and receivers, which are to take the return water from the steam-heating system and pump it back to the boilers, the two tunnels leading off to all the buildings on the campus, and the hopper under the railroad track, where coal will be received and conveyed by machinery to the bunkers in the boiler room. He further explained that the boilers, coal-handling machinery, pumps and other equipment were designed so that tests of each part of the plant or the plant as a whole may easily be made by the students of mechanical and electrical engineering.

E. C. JOHNSON,
Branch Chairman.

COLUMBIA UNIVERSITY

The United Engineering Society held a joint meeting with the Mining Society on January 17, when the speakers of the evening were Charles Piez, Mem.Am.Soc.M.E., on The Art of Conveying Materials, J. P. Channing on Human Engineering, and Fred H. Rindge on The Industrial Service Movement of the Y. M. C. A.

J. L. KRETZMER,
Branch Chairman.

JOHNS HOPKINS UNIVERSITY

The first meeting of the Johns Hopkins University Student Branch was held December 15, 1916, and the following officers elected: President, Edward Stewart; vice-president, A. McWolfe; treasurer, N. Owings; and secretary, B. A. Sullivan.

On January 17 the Branch was addressed by J. O. Martin, of the Chesapeake & Potomac Telephone Co., of Baltimore, Md. His subject, The Romance of the Telephone, was exhaustively treated, and the many interesting slides shown gave the students a good insight into past and present telephone work.

B. A. SULLIVAN,
Branch Secretary.

KANSAS STATE AGRICULTURAL COLLEGE

Walter W. Carlson, Mem.Am.Soc.M.E., professor of mechanical engineering and shop practice at the Kansas State Agricultural College, gave an illustrated lecture on The Future Incomes of College Engineers, before the Student Branch of that college on January 18. The curves on the charts displayed, were drawn from data taken from several of the most representative colleges in America, and formulæ were derived whereby a student may roughly foretell his income at any year after graduation. The following table shows the formulæ for the average student: (X equals number of years after graduation).

All Colleges	750 + 170X	Salary	(year)	Max.	in	20	years
K. S. A. C.......	600 + 200X	"	"	"	"	20	"
Trade School...	150 + 125X	"	"	"	"	10	"
Shop Training...	150 + 90X	"	"	"	"	8	"
Laborer	200 + 100X	"	"	"	"	5	"

W. N. CATON,
Branch Secretary.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

The Massachusetts Institute of Technology held their first smoker of the new term on the evening of February 9. The first speaker was R. H. Sawyer, '17. He briefly outlined the process of paper manufacture and described some of the important machinery used in the work. The second speaker was T. K. Corey, of the Wm. Filene Sons Co., Boston, who is in charge of the 2500 employees of the company and was therefore in position to ably handle the subject of Human Engineering. He particularly emphasized the necessity of coöperation between the employer and employee in order to assure satisfaction and contentment on both sides. Mr. Corey kindly extended to the students an invitation to visit the plant to view a few of its mechanical features, which include a complete power station and boiler house, located six floors below the street, a refrigerating plant and a large wireless station.

EDW. W. ROUNDS,
Branch Secretary.

NEW YORK UNIVERSITY

An interesting talk on Water Power Plant Design was given at the February 9 meeting of the Student Branch of New York University by H. M. Garson. An hour of lively discussion followed.

JOSEPH GILMAN,
Branch Secretary.

POLYTECHNIC INSTITUTE OF BROOKLYN

At the February 13 meeting of the Student Branch of the Brooklyn Polytechnic Institute the two speakers were Bronson L. Huestis, Mem.Am.Soc.M.E., and Samuel Stern of the class of '17.

Mr. Huestis' subject was Materials and Manufacture of Mixed Paints. He described in detail the various kinds of pigments and solvents, enumerating their advantages and disadvantages. He said paints containing adulterants, such as clay, whiting, barium sulphate, etc., in their proper proportions, make better paints than the pure substances alone.

A discussion on The Development of the Phonograph was given next by Mr. Stern. He explained the operation of the diaphragm, the construction of the sound-box, the speed regulation of the motor and the different types of motor used.

President Hollis delivered an interesting lecture before 300 students of the Institute on February 14, on the subject of Service to Our Country. He stated that we all ought to be ready to give our service to our country whenever needed. Although there had been no definite call for service, he sincerely believed that if the test should come no man in the United States would be found wanting. Dr. Hollis emphasized the word Service, bringing out the fact that Congress, in discussing compulsory military service laws, laid too much stress on the word *military*, rather than *service*. If our country should be involved in war, fully one-third of the men would do more useful service in the factories than in the Army or Navy.

He stated that in his opinion war would never cease, unless some substitute were found where men could sacrifice themselves for their country, with the same spirit that they do on the battlefield. He really believed that that incentive existed, if we would only look for it. He pointed out the difference between democracy, autocracy and nationalism, defining a democracy as a place where man has permission to develop himself to a maximum efficiency. Democracy was bound to fail unless men could develop them-

selves to that efficiency to which they are forced under nationalism. There is much room for better efficiency in this country, since in no country in the world is there as much waste as in the United States.

In reporting the January 6 meeting it was neglected to state that Mr. Rosenzweig's talk was accompanied by a number of slides showing the poppet-valve engine of his own design. He also gave a description of his return flow and uniflow types as built by the York Mfg. Co., York, Pa.

George Cherr,
Branch Secretary.

PURDUE UNIVERSITY

The Reasons Why Chinese Industries Have Not Progressed, was the subject of the talk T. S. Yue, a senior mechanical student, gave before the Student Branch of Purdue University at their meeting on January 22. The reasons he gave were the retardation of ethical teachings, political oppression, and the social and home bondage. As a remedy for the first two he suggested the republican form of government now existing, and as an aid to the latter the completion of the railroads now contemplated.

The meeting held by the Purdue Branch on February 7 was of an informal nature. Professor Aitkenhead, of the Farm Mechanics' department of the School of Agriculture, initiated those present into the mysteries of the square, the single and double bowline, the catspaw and other useful knots, as well as several types of rope splicing.

W. G. Schutt,
Branch Secretary.

STATE UNIVERSITY OF KENTUCKY

The Student Branch at the State University of Kentucky has held three business meetings during the college year. Several other meetings have been held which have been devoted entirely to the study of technical magazines, each member reporting on the contents of the particular journal assigned to him. In this way a large number of the engineering problems confronting the technical graduate are brought into discussion.

At the meeting on February 8 an interesting discussion of the development of the steel industry was given by Governor A. O. Stanley.

D. S. Springer,
Branch Secretary.

STEVENS INSTITUTE OF TECHNOLOGY

The Stevens Engineering Society, which includes the Student Branch of the Am.Soc.M.E., announces that it will resume its schedule of inspection trips on February 21. Among the trips planned are those to the Shadyside Plant of the Barrett Mfg. Co., Loose Wiles Biscuit Co., Hoboken Factory Terminal and the Nagel Packing House.

Alvin G. Searles,
Branch Secretary.

UNIVERSITY OF CALIFORNIA

The first regular semi-monthly meeting of the Student Branch of the University of California for the second semester was held on January 31. Herman Greenwood tendered his resignation as chairman and W. Kenneth Potts was elected to take his place. At its close, Leroy Hill read a paper discussing at length the theory, practice and use of the various types of aeroplane-motor radiators, describing and illustrating the models and showing by comparison the various proportions and sizes used by different manufacturers.

John H. Fenton,
Branch Secretary.

UNIVERSITY OF COLORADO

Mr. Welch of the Strait Scale Co., Boulder, Colo., gave an interesting illustrated talk on The Construction and Operation of Scales at the January 11 meeting of the Student Branch of the University of Colorado. A large aluminum model, which Mr. Welch brought with him, served to show in detail the fine points of construction and the method of operation of the scale. He claimed that the fundaments of scale operation are the power of ratio, and the perfection of the alignment of the knife edges, and that scale errors depend solely upon the distance between pivots and not on scale ratio.

Wayne S. Beattie,
Branch Secretary.

UNIVERSITY OF ILLINOIS

On the evening of February 8 the Student Branch of the University of Illinois met for the election of officers for the coming semester. The new officers are: President, Ralph M. Overton; vice-president, F. E. Evans; secretary, H. C. Dieserud, and treasurer, W. Minkema. The work of the semester is quite promising, several lectures being already scheduled.

H. C. Dieserud,
Branch Secretary.

UNIVERSITY OF MAINE

The University of Maine Branch held their regular monthly meeting January 17, the subject for discussion being The Farm Tractor. Numerous pictures of the tractor in action were shown by means of a reflectoscope, which testified to its adaptability and usefulness to farmers all over the country. Several interesting designs of the machine were shown, their history given, and salient points discussed.

R. E. Fraser,
Branch Secretary.

UNIVERSITY OF MICHIGAN

Ball Bearings was the subject of the first lecture of the year, given January 16, before the University of Michigan Student Branch by F. M. Sawin. Stereopticon slides illustrated the modern improvements on ball bearings and the process of manufacture from the raw material to the finished product.

The January 18 meeting was devoted to the election of the following officers: chairman, W. A. McKinley; vice-chairman, W. C. Good; secretary, Karl Bintz; treasurer, E. F. Jagodzinski.

Karl Bintz,
Branch Secretary.

UNIVERSITY OF MINNESOTA

The Student Branch of the University of Minnesota held a meeting on January 20 when the following officers were elected: president, Edwin F. Jones, vice-president, L. N. Eustis; corresponding secretary, H. G. Fortune; recording secretary, J. Walfred; treasurer, G. N. Moffet. Following the election, Prof. J. J. Flather, Mem.Am.Soc.M.E., head of the mechanical engineering department of the University, read and discussed the Report of the Boiler Code Committee.

C. Q. Swenson,
Corresponding Secretary.

WORCESTER POLYTECHNIC INSTITUTE

On Friday evening, February 2, the Worcester Polytechnic Student Branch held their regular monthly meeting, Charles M. Allen, Mem.Am.Soc.M.E., and Professor of Hydraulic Engineering at the Institute, giving an interesting illustrated talk on The Testing of Water Wheels After Installation.

As a consulting engineer, Professor Allen had occasion to test many installations of water wheels in hydroelectric plants, and the lantern slides evidenced the work done under the most varying conditions, from that in which the building had been built around the machinery in some backwoods ravine to an installation of the most up-to-date sort, in which the building was provided with spur tracks, traveling cranes and other appliances, making the installation of the dynamometers a comparatively easy matter. He emphasized the facts that water wheels should be tested after installation to show whether or not they were so set as to give their full power and efficiency rating; that all power stations should be provided with the proper cranes and appliances for installing heavy machinery and for future repair purposes.

H. P. Fairfield,
Branch Secretary.

EMPLOYMENT BULLETIN

***THE SECRETARY** considers it a special obligation and pleasant duty to make the office of the Society the medium for assisting members to secure positions, by putting them in touch with special opportunities for which their training and experience qualify them, and for helping any-one desiring engineering services. The Society acts only as a clearing house in these matters.*

POSITIONS AVAILABLE

In forwarding applications, stamps should be enclosed for transmittal to advertisers; applications from non-members should be accompanied by a letter of reference or introduction from a member, such reference letter to be filed with the Society. Copy for notices must be in hand by the 15th of the month.

PARTNERSHIP. Present owner desires capable assistant in running a business which is well established. Investment of $20,000 to $25,000 required, as well as practical working interest in business near Philadelphia engaged in operation on a limited scale for making silica brick. 522

DRAFTSMAN, capable of designing machines of comparatively large size for boring and milling purposes, and fixtures and tools for use on such machines. Location Providence. 525

CHEMICAL ENGINEER who is experienced in aniline-dye manufacturing to become department engineer. Position pays $40-$75 per week, depending upon the man's ability. Name confidential. Location New York State. 530

DRAFTSMAN experienced in factory design and installation of elevator and conveying machinery in general cement-plant work. Location Pennsylvania. 710.

DRAFTSMAN. Prefer man with one or two years' experience out of college. Location Virginia. 747

DESIGNER. Expert mechanical engineer qualified to design machinery for the manufacture of shaving brushes. Location New York. Name confidential. 757

FOREIGN REPRESENTATIVE. New York firm desires a competent man with knowledge of machinery to take charge of machinery business in France; must speak the French language fluently. 758

ENGINEERS wanted to train and develop in the fundamentals of a firm primarily engaged in the distillation of coal tar with the resultant principal production of bituminous road and roofing materials, with the ultimate object of filling operating positions in various plants as foremen, head chemist, assistant superintendents, or superintendents. Chemical engineering training desirable but not essential. As contemplated work will eventually be of an executive nature, ability to handle men is a desirable asset. 796.

DRAFTSMEN, with special experience in the design of chemical plant equipment; familiar with power-plant design, piping layouts, foundation work, light structural-steel work and timber-platform construction. Location Brooklyn. 803.

FOUNDRY MANAGER with capital to invest in gray-iron foundry. Location Northern Ohio. 808.

DRAFTSMAN on elevating and conveying machinery and light structural and plate work. Permanent employment to desirable man, with opportunities for advancement. Salary $125 per month to an experienced man. Location Hudson, N. Y. 809.

ELECTRICAL ENGINEER possessing extensive experience with electrolytic plants for producing oxygen and hydrogen, wanted by New York concern. 811.

CHIEF ENGINEER for large central-station power house in an Atlantic seaboard city. Must be qualified to take charge of an 80,000-kw. plant and experienced in handling Curtiss turbines, jet and surface condensers, Taylor stokers, and other apparatus found in large central-station plants. State age, experience and salary expected. If employed, give name of company and reason for changing. All replies strictly confidential. 813.

ASSISTANT to the head of engineering department of Boston concern. Young technical graduate, mechanical or engineering course. Salary $100 a month; good chance for advancement. 817.

SALES CORRESPONDENT and TRAVELING SALESMAN, two men who know machinery, preferably equipment used either in paper mills or factories working on paper as a raw material such as printers, box makers, bag, envelope or paper-specialty manufacturers. Engineering degree not necessary, but character, ability, energy and clean record are. Salary $1,500 per year after instruction period, increasing with ability. Prefer letter outlining record before interview. Location Brooklyn, New York. 820-821.

OFFICE INSPECTOR to show how to improve work. Experienced in foundry work and machine-shop tool work. Salary according to man, say $2,000 to start. New York location. 822.

CHIEF DRAFTSMAN for large malleable-iron foundry, with pattern, machine, and smith shops and finishing department. Output consists principally of railway specialties. Experience required in charge of drafting-room work, steel freight car construction, both body and trucks, design of special shop equipment such as molding machines, tools, jigs and fixtures, the installation of power-transmission machinery. Prefer a young man who has had experience either with a railroad or a car builder, who is personally quick, accurate and of pleasing address, able to secure results from the men under him. Salary, $150 to $175 per month; prospect good for promotion to the right man. Location New York State. 823.

ENGINEER OF TESTS. Young man of more or less technical training in mechanical engineering, to be of assistance to the engineer in general testing work on boilers, engines and turbines. Salary to start, about $15 per week. Location New York. 824.

DESIGNER and ASSISTANT ENGINEER on power-plant work, both mechanical and electrical side; must have had experience in this line of work. Location New York. 825.

EXECUTIVE to take charge of grab-bucket department of structural-steel plant. 845

TWO SALESMEN or SALES REPRESENTATIVES, 25 to 30 years of age, unmarried, energetic and intelligent. Technical and selling experience, with knowledge of accessory business required, although would consider competent and experienced salesmen without technical training. Position requires ability to sell to jobbers and develop large territory. Salary $45 to $50 per week with traveling expenses. Territory: Middle West and South, and West, respectively. 863

SALES ENGINEERS, technical training, two or more years' practical experience in selling, to coöperate with salesmen in various districts in the U. S. to further the sale of lineshaft roller bearings. Salary $1,200 to $1,800. 864

DRAFTSMAN, technical graduate, mechanical engineer, one or two years' experience in designing power-house installations; water-, steam- and air-piping systems, for large manufacturing concern near Philadelphia. State age, experience to date, references, salary desired, and how soon available. 865

DRAFTSMAN, familiar with marine-engine and boiler work, preferably man with some experience in hull work. State age, salary, experience and references. 869

EXPERIENCED TIME-STUDY MAN, familiar with the production of small interchangeable parts, wanted for manufacturing plant in Philadelphia. Position will lead to one of responsibility. 826.

CHIEF DRAFTSMAN or ASSISTANT ENGINEER to handle primarily steam piping. Salary $175. Location New York. 827.

ASSISTANT ENGINEER, with technical training and a successful record in the operation and maintenance of power plants and factories—also handling of men. Hours at present 7 a.m. to 5:30 p.m. Salary to start, $200 per month. Excellent opportunity for advancement for a man of initiative and energy. Location Brooklyn. 830.

DRAFTSMAN on machine-shop equipment—jigs, tools, etc. State experience and salary expected. Location Canada. 838.

SUPERINTENDENT and **MECHANICAL ENGINEER**. Good opportunity for young man to start with a new, growing concern; one who has experience on conveyors and sawmill and pulp mill machinery. State fully experience and give references. Location Michigan. S42.

SALES ENGINEER for established Detroit concern, manufacturers of boiler accessories. Salary commensurate with experience and ability. Must be thoroughly acquainted with boilers and be able to successfully meet and impress technically trained executives, and capable of closing contracts ranging from $300 to $10,000. Write explicitly, giving experience, minimum salary to start and references. Correspondence confidential. Address E. C. W. 80 First Street, Detroit, Mich. S53.

MECHANICAL DRAFTSMEN for small [illegible] works. Salary $18-$20 and $20-$25. Men that have [illegible] "know how and why." Location Newark, N. J. S55-S56.

DRAFTSMAN to design transmission machinery. Salary $30 per week. Location New York. S57.

ENGINEERING APPRENTICES. Openings for two recent technical graduates, with opportunity for experience in steam turbine manufacture, testing and designing. Salary $15 per week for first nine months. Will also consider 1917 graduates, to begin work in June or July. Location Connecticut. S59.

CHEMICAL ENGINEER for a permanent position in the Philippines. One who has had considerable experience in extracting plants and understands the extraction of oils from cake with trichlorethylene, carbon tetrachloride, naphtha, etc. Must be more or less familiar with the refining of vegetable oils and soap manufacturing. Correspondence will be carried on through New York office. S60.

DRAFTSMAN for machine design and small tool work. Young man with some experience. "Live wire." Salary depends on man. Location New York. S61.

ENGINEER experienced in milling graphite by wet process, to take up construction of new plant. Salary depends on man. Location Alabama. S12.

EFFICIENCY ENGINEER for general efficiency work in car manufacturing plants. In replying state age, experience and salary expected. Probable location, Canada. S70

MECHANICAL ENGINEERS of highest type—especially experienced in steel machinery, designing and building, wanted for newly organized plant; must be able to handle men. Give age, previous experience. Probable location Middle West. S71

MASSACHUSETTS concern wants technically trained man, about 30 years of age, married, who has brains, personality and tact. Write stating full particulars. S72

WORKS ENGINEER. Highly experienced [illegible] power and construction matters in rapidly [illegible] employing 3000. Must be active and tactful and of demonstrated [illegible]. Preference to man with technical training. In first [illegible] salary and complete statement of experience. Location [illegible] West. S77.

CAPABLE MAN, with experience in [illegible] and repair, for position as traveling service inspector [illegible] Wisconsin. S78

MEN AVAILABLE

Only members of the Society are listed in the published notices in this section. Copy for notices should be in hand by the 15th of the month, and the form of the notice should be such that the initial words indicate the classification. Notices are not repeated in consecutive issues.

MECHANICAL ENGINEER or **ASSISTANT SUPERINTENDENT**, technical graduate, age 30, married. Seven years' experience in manufacturing plants as draftsman, mechanical engineer and division superintendent and in planning production and time-study work. Ambitious and desirous of locating with Eastern concern offering good opportunity. C-104

PURCHASING AGENT, with several years' experience with large manufacturing concern, where practical mechanical knowledge was applicable. Familiar with stock-room systems, a close buyer and resourceful. Available on reasonable notice; location immaterial. C-105

INDUSTRIAL PLANT ENGINEER, graduate M. E., aged 30, desires position with growing concern as engineer or assistant engineer, depending upon size of plant. Nine years' [illegible] power plant, construction and maintenance [illegible] in purchasing. Successful in handling men and [illegible] correspondent. Location East or South preferred. C-106.

ENGINEER, with twenty-five years' experience in organizing, manufacturing and operating steam, gas and electrical machinery with some of the largest builders. Competent to take charge of entire manufacturing plant. Desires position where new ideas and personal services may lead to an interest in firm. Ohio, Indiana or Western Pennsylvania preferred. C-107

MECHANICAL ENGINEER or **ASSISTANT SUPERINTENDENT**. M. E. graduate, age 31, married. Seven years' experience on automobiles, motor trucks, accessories, production tools, small punch and die work, inspection gages and a large variety of small and medium special and semi-automatic machinery. Capable of directing as well as executing work. Would like to join small or medium-sized growing organization. At present employed as assistant chief engineer. Present salary $2100. C-108

EXECUTIVE or **MECHANICAL ENGINEER** experienced in factory organization and design of special elevating and conveying machinery, tools and jigs. Technical graduate; desires opportunity with reliable firm. Location New York or vicinity. C-109

MECHANICAL ENGINEER desires position in connection with maintenance or production of railway rolling stock and equipment or production of mechanical equipment incident to preparedness for national defense. At present employed. Twenty years' experience in design and construction of industrial and railway mechanical equipment; highly specialized in practical application of applied science, locomotives, cars, trucks, boilers, engines, turbines, tanks and special machinery, shop layouts and power plants, towers and structural work. C-110

MECHANICAL ENGINEER, technically educated, desires to make change. Fifteen years' experience in the designing, estimating and development of steam shovels, dredges, hoisting engines, derricks and miscellaneous machinery, with some steel-foundry and machine-shop practice. Location in Middle West preferred. At present employed. C-111

ASSISTANT SUPERINTENDENT, M. E. graduate, with eight years' shop experience. Familiar with modern methods in quantity production and capable of producing results and handling men. C-112

EMPLOYMENT MANAGER. Technical graduate, with the proper training and experience, age 31, married. Available after May 1. C-113

MECHANICAL ENGINEER, age 37, would consider partnership or interest in engineering business or position on salary or salary and commission basis. Technical graduate, fourteen years' foreign and domestic experience in designing, selling and erecting water turbines, governors, penstocks and accessories and in making preliminary investigations and reports on water-power projects and efficiency tests on existing plants with a view to making improvements. Well grounded in steam and electrical engineering; several months in charge of gasoline-tractor design. Thoroughly practical, with executive ability, and not afraid of work or responsibility. At present employed but desires change. Location preferably East or South. Best references. C-114

MECHANICAL ENGINEER. Technical graduate in mechanical engineering. Desires position with industrial plant as plant or maintenance engineer. At present employed. Several years' experience in drafting, structural work, and as engineer for large explosives company. Preferable location, Middle West. C-115

RESEARCH ENGINEER, PROFESSOR OF MECHANICAL ENGINEERING, EXPERIMENTAL or **WORKS ENGINEER.** An experienced mechanical and civil engineer, now engaged in munition manufacture, is open for engagement. Graduate of leading university, member S. A. E., experienced in teaching and in engineering work of all kinds. Would consider locating in England or France. C-116

CHIEF ENGINEER, who has held the positions of chief engineer, master mechanic and chief draftsman in large industrial plants. Thorough technical and practical experience, covering construction and operation and upkeep of steam and hydraulic power plants. Specialty, steam and fuel economy. Would consider a change from present position. Salary $2400 per year. C-117

ASSISTANT WORKS ENGINEER, college graduate, 6 years' experience; 3 years of arrangement and installation of turbines, boilers

coal-handling equipment, gas producers, heating and lighting systems, 1 year of machine design, and 1 year of building construction. At present employed. Desires permanent location in Philadelphia or vicinity. C-75

POSITION IN PUBLICITY DEPARTMENT of large mechanical or electrical concern or with a publicity engineer wanted by M. I. T. graduate with broad newspaper experience, future the primary consideration. At present employed in an engineering position. Best of references. C-76

MAINTENANCE ENGINEER or MECHANICAL ENGINEER, Junior Member, Columbia M.E., age 25. Thorough shop, power plant and construction experience, design of special machinery, supervising construction and installation. At present employed. Salary $1500. C-77

POWER PLANT ENGINEER, practical in the designing, building and maintenance of power plants in detail. Now employed. Available at short notice. C-78

PARTNER. Graduate mechanical engineer, age 35, having several years' broad and successful experience as factory manager, wishes to correspond with view to handling the factory end for persons intending to organize a manufacturing business. C-79

MECHANICAL ENGINEER, age 22, technical graduate, member A. S. T. M., with drafting-room and some factory experience and knowledge of accounting, desires situation with manufacturing or engineering firm in or near Boston, if possible. At present employed; good reasons for desiring to make change. C-80

WORKS MANAGER, CHIEF ENGINEER OR GENERAL SUPERINTENDENT, desires to locate within a radius of 100 miles from New York City. A 1 systematizer, organizer and production man with excellent executive ability and able to produce results. American, 44 years of age, with 18 years' practical executive experience in the positions of chief draftsman, general superintendent and works manager on light and medium-heavy interchangeable parts as used on typewriters, moving-picture machines, gasoline and electric autotrucks, water meters, linotype machines, automatic machinery and machine tools, etc. C-81

MASTER MECHANIC or CHIEF DRAFTSMAN, with 15 years' experience on automatic machinery. Salary $2600. C-82.

ENGINEERING EXECUTIVE and SALES ENGINEER, aged 31, married. Have organized and managed both machinery and retail sales forces. Shop experience in machine-tool works. Started and developed a successful retail business which has been recently bought. Location preferred New York City or New Jersey. C-83

STOREKEEPER and PLANNING DEPARTMENT MAN, married, ten years' experience. Salary $35 per week. C-84

DESIGNING ENGINEER, age 30, married. Ten years' experience, English and American, in commercial trucks, tractors and motor fire apparatus; exceptional experience on front-wheel-drive trucks. Fully conversant with interchangeable manufacture. Assoc. Mem. A.S.M.E., Inst. Mech. Engineers (London). Minimum salary $2400. C-85.

ASSISTANT to EXECUTIVE or WORKS MANAGER, age 29, married. Technical graduate, six years' experience in industrial engineering design and construction of buildings, installation of machinery, purchase of equipment and handling of men. At present employed, but wishes position in operating work. Best references. Immediate salary subordinate to future prospects. C-86

MECHANICAL ENGINEER, age 32, now mechanical superintendent of one of the largest cotton mills, would like opportunity to prove that he is capable of handling higher position in mill or high class consulting engineer's office. Considers hard work a pleasure. C-87.

STUDENT MEMBER. Will graduate in June in mechanical engineering course of Bucknell University. One year of practical drafting and two years' practical experience in general repair shop. Free to go wherever there is a chance for advancement. References upon application. C-88

MECHANICAL SUPERINTENDENT or CHIEF ENGINEER, graduate in mechanical engineering, age 38. Fifteen years' experience, ten of which were in charge of power generation, construction and maintenance in large industrial plant. Good references from present employer. C-89

SALES ENGINEER, practical machinist, age 31, married. Technical graduate, with experience in drafting room, plant operation and selling. Now holding position where not only first-class salesmanship but also good engineering ability is very essential. Desires change and would be available in 30 days to one who is looking for an aggressive, capable man of integrity who will push a line with merit, preferably on salary and commission, or on straight salary or straight commission basis. C-90

SUPERVISING ENGINEER, age 28. Technical man, hustler, at present with manufacturing drug concern in charge of construction, light, heat, power, sprinklers and plumbing. Desires change for bigger opportunity. Good, varied experience in labor-saving methods, planning factory layouts, buying and maintenance of equipment and power plants. C-91

PRODUCTION or WORKS MANAGER, age 40. Twenty-one years' experience in time keeping, costs, buying, selling, piece work, planning and production. Thoroughly capable in both office and factory organization; competent to assume responsibility and produce results. Minimum salary $2800. C-92

TECHNICAL GRADUATE, age 23, desires position in manufacturing line. Twenty months' practical experience. Good knowledge in design of small electrical machines. Study of power-plant operation and design. Thorough knowledge of internal-combustion motors and automobiles. Salary $100 per month to start. Location preferred New York. C-93

COMPETENT ASSISTANT to EXECUTIVE. Graduate of Mass. Institute of Technology (1910), has made good in a large munition plant. Now employed but wants a change. Can give references. Salary $2500. C-94

WORKS MANAGER, with successful experience in manufacture of interchangeable parts and shrapnel shells. Chicago vicinity preferred though not essential. C-95

SALES ENGINEER. Mechanical engineer, opening sales office in Chicago in near future, wishes to handle power-plant machinery and specialties on salary or commission basis. Familiar through experience in plant engineering and management with conditions to be met in manufacturing and power plants. C-96

PLANT ENGINEER. Competent to lay out electrical and mechanical transmission and power-plant work in general, and to maintain and improve structures and grounds. At present employed directing work. Prefers large industrial concern. C-97

WORKS MANAGER OR GENERAL SUPERINTENDENT. Production engineer, successful executive; experienced in revising plant management and in the introduction of modern systems. Technical graduate, 20 years' experience in positions from foreman to manager of works employing several hundred men, covering manufacture of machine tools, internal-combustion and steam engines, electrical machinery and construction of works. Available in about 60 days. C-98

EXECUTIVE ENGINEER. Graduate in mechanical engineering, 1907, with exceptional training in mechanical and electrical fields as executive and engineer in construction, sales and accounting work. A consequential thinker, with energy, initiative and aggressiveness. Can consider a proposition where intelligence and ability to "cash in" ten years of hard-earned and valuable experience will bring results. C-99

PARTNERSHIP. Mechanical engineer desires partnership in consulting engineering or contracting firm doing business with industrial concerns. Will make investment. Specialties: power-plant design, construction and operation; industrial plant layout; design of special machinery. Familiar with brass and copper mill practice. C-100

MECHANICAL ENGINEER. Technical graduate, with six years' experience in the design and manufacture of and experimental work on valves, lubricators and general brass goods. At present head draftsman. Systematic and reliable, possessing originality and initiative. Desires position with a responsible future. C-101

ASSISTANT SUPERINTENDENT or EXECUTIVE. American, age 36. Technical education, twelve years in drafting room, including position as chief draftsman; six years' shop experience, one as foreman of shop. Practical mechanic, familiar with the design of special machinery, tools, jigs, fixtures, etc., for manufacturing duplicate parts on the interchangeable system. Salary $2000 per annum. Location preferred New York or vicinity. C-102

ASSISTANT to MANUFACTURING EXECUTIVE, technical graduate, age 31. Familiar with manufacturing practice, production, construction and handling men. Good knowledge of purchasing. Desires position with future. C-103

ENGINEERING SURVEY

A Review of Engineering Publications in All Languages. All the leading periodicals of the engineering world, embracing over 1000 different publications, are received at the Library. These are systematically examined for review each month in the Survey.

SUBJECTS OF ABSTRACTS

ARRANGED IN THE ORDER OF THEIR APPEARANCE IN THE SURVEY

In the past month in the Grand Central Palace, New York City, two expositions were held which were closely related in many respects. The first was the Motor Boat Show and the second, the first Pan-American Aeronautic Exposition. Both bore in the first place testimony to the triumph of internal-combustion engineering and in particular to the development of the explosion engine. Both showed that some of the problems of this comparatively new branch of engineering may be considered as having been solved satisfactorily. Such are the problems of ignition, lubrication and water cooling. The question of air-cooling design appears to be still under a cloud of doubt. The problem of fuel is fully solved in so far as gasolines are concerned, but when we come to kerosenes there is still a wide field open for further research and invention. It appears, however, from a paper read at the last annual meeting of the S.A.E., that even here a large amount of success has been achieved; there are several designs of kerosene carburetors practically available which can efficiently handle the heavier fuels (as compared with the gasolines), and the most important problem now before the designer of a kerosene-burning engine is not the carburetor but the combustion chamber.

As regards the Aeronautic Show, the most striking feature of it to those who have closely followed the vicissitudes of the early days of heavier-than-air-machine building are the truly tremendous strides made in the last two years. To the aeronautical industry the war has certainly been a big opportunity. No precise data are of course available as to the number of machines used by the belligerent countries, but Captain Clarke, U.S.A., at a recent meeting of the S.A.E., gave those present to understand that the French alone have not less than 20,000 planes. From various sources one can glean that the number of British machines is at least as large, which would mean that the two great allied nations alone have something like 40,000 machines, representing an establishment worth, with its shops and auxiliaries, not less than the stupendous sum of $500,000,000; all of this spent in something like twenty-four months. There certainly never has been an instance where a new industry, less than ten years old, has been given such an opportunity. How fully it has made use of it can be determined only after an investigation of what has been done in Europe, which is unfortunately impossible at the present time.

THIS MONTH'S ARTICLES

In the section Air Engineering is described a fan capable of separating water and dust from the air by a process similar to that of centrifugation.

In the same section is abstracted a university thesis on the flow of air through nozzles and orifices. Particular attention is called to this work, as it contains English translations of the most important investigations on this subject for the last century. Unfortunately, some of the formulæ are printed in such a manner as to make their meaning doubtful.

Under Automobiles is described a British farm tractor employing broad-treaded rollers instead of the usual driving wheels. In the same section is described a unique system of spring lubrication.

From a British publication is abstracted the description of a belt-conveyor coal-loading plant having several unusual features of design.

F. N. Speller, in a paper before The American Society of Heating and Ventilating Engineers, describes an experimental plant installed for testing a method of elimination of corrosion in hot-water-supply pipe by fixation of oxygen in water before the water is admitted to the pipes.

J. O. Ross, in a paper before the same society, discusses the fundamental principles underlying the design of driers and the fields of service of various types of this class of machinery.

Results of an experimental investigation of the brittleness produced in steel springs by electroplating are presented in the section Engineering Materials. While no explanation of this brittleness has been found, the results are of a certain practical interest.

Cast iron for engine cylinders is the subject of a paper by J. Edgar Hurst before the Manchester Association of Engineers. The paper presents interesting material on the subject of the growth of alloys.

Formulæ on measuring gases by a standard orifice are reported in a composite abstract of papers by Prof. Thomas G. Estep and H. G. Geissinger.

The somewhat unexpected fact that gas-heated rivets remained hot longer than those oil-heated is brought forward in the *Bulletin of the Southern Gas Association.*

From *The Engineer* (London) is taken a description of a high-lift centrifugal pump, of interest particularly because of the automatic hydraulic balancing arrangement used.

Data on comparative costs of steam and electric operation of hydraulic-elevator pumps are abstracted from an article in the *Electrical Review and Western Electrician.*

A description of an experimental refrigerator car of the Pennsylvania Railroad, combining features of passenger- and freight-car construction, will be found in the section Railroad Engineering.

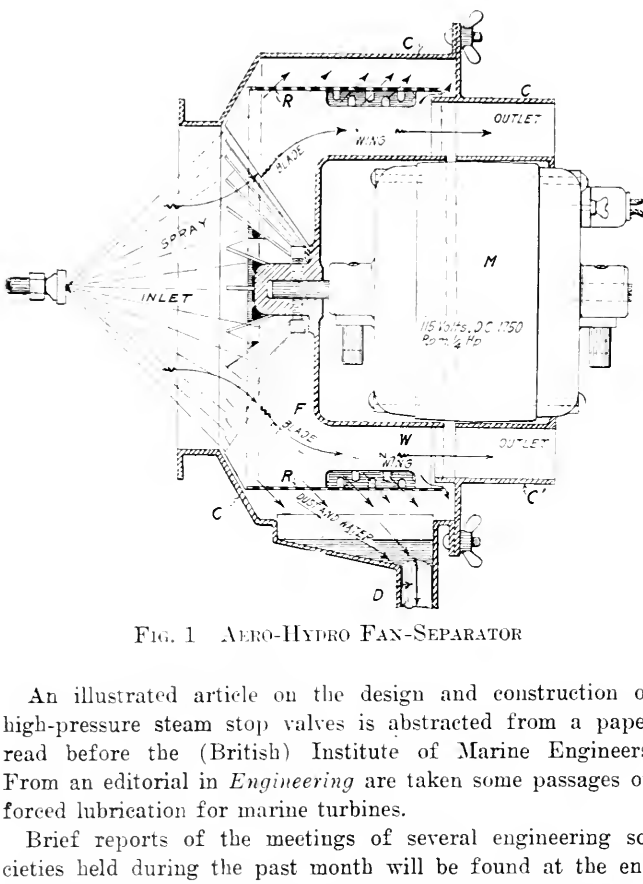

FIG. 1 AERO-HYDRO FAN-SEPARATOR

An illustrated article on the design and construction of high-pressure steam stop valves is abstracted from a paper read before the (British) Institute of Marine Engineers. From an editorial in *Engineering* are taken some passages on forced lubrication for marine turbines.

Brief reports of the meetings of several engineering societies held during the past month will be found at the end of the Survey, as well as more complete accounts of the Motor Boat Show and Pan-American Aeronautic Exposition.

Air Machinery

AERO-HYDRO FAN-SEPARATOR, Wm. J. Baldwin

Description of an improved fan capable of separating water or watery matter or dust from the air. The apparatus dealt with in the article is designed for a hospital ship and is located in a deadlight. The diameter of the hole in the ship's side, which is the inlet, is 8½ in., and the greatest diameter of the apparatus over its flanges is 14 in. Its capacity is 35,000 cu. ft. of air per hour and it permits of keeping the portholes open even in rainy or bad weather.

In Fig. 1, which is a longitudinal section through the apparatus, C and C' represent the stationary case and F the fan revolving within the case. The motor M is fastened to the outlet port of the case C, and the shaft carries the fan F and the rotor R with the wings W. The revolving part is made of aluminum and weighs 7 lb. The plates of the fan are radial and straight so that the apparatus can be run in either direction, any way the current happens to be applied.

When water or spray enters the inlet it strikes the blades of the fan, and, being heavier than the air, goes off almost perpendicularly to the axis of rotation, striking the rotor and being thrown through it about as indicated by the straight arrows. In this way the water escapes at the pipe D and runs outward through a small piece of flexible hose to the deck of the ship or overboard. The air follows the direction of the feathered arrows. It has been found that with the finest spray nozzles that can be obtained the hygrometric condition at the outlet of the cabin end of the apparatus is from 45 to 50 per cent of saturation, and the peculiarity of the apparatus is that even in fog the water will seize on the fog and carry it with it through the rotor, the air escaping into the cabin still showing about 50 per cent of saturation.

The author enumerates many uses for the apparatus described, especially in the field of dust separation. Among these he describes experiments with high-temperature-furnace fumes in a plant where, after the detinning process is completed, the old cans are made into sash weights. By means of the separator they have succeeded in recovering the dust and gases from the top of the cupola, with temperatures probably above 1200 deg., and have taken the tin, lead, zinc, etc., from the gases by the use of the wet process, throwing them into a tank as a mud. This example is cited to show that fumes from gases and metals can be treated at very high temperatures. (*Journal of the American Society of Heating and Ventilating Engineers,* vol. 23, no. 2, January 1917, pp. 209-215, 6 figs, *de*)

THE FLOW OF AIR THROUGH NOZZLES AND ORIFICES, J. Lynn Reynolds and Homer J. Ling

Historical review of the development of the theory of flow of air through orifices, comprising a number of translations and abstractions of various writers of the nineteenth and present centuries, beginning with Koch, Buff, and Saint Venant and ending with Captain Morley, thus bringing the review down to within a year of the present day.

The second part of the work is devoted to a discussion of the design of needle nozzles. .

As regards the general theory of flow of air through orifices and nozzles with special regard to problems of measurement, the writers believe that the main reason why the nozzle-and-orifice method for measuring the discharge of air has been discredited is due to the ambiguous presentation of data by different experimenters, which led to the use of improper coefficients with the given orifices or nozzles in cases where, if proper coefficients were used, the results would have been satisfactory. Further, the actual discharge of air through a given nozzle or orifice is less than the theoretical discharge under identical conditions of pressure and temperature. This is due to the fact that as a general rule the stream of air has a smaller cross-section than that of the orifice itself. Also, because of internal and external frictions, the effective velocity of flow is less than the theoretical value. With the thin-edge orifices the coefficient of velocity is practically unity, that is,

the orifice is considered to be frictionless; in which case the coefficient of discharge may be considered equal to the coefficient of contraction.

When these two factors, *vena contracta* and diminished velocity, are taken into account, it necessarily follows that the measured discharge is a smaller quantity than the value given by the theoretical formula. The writers note that if a = coefficient of contraction, and b = coefficient of velocity, then ab = coefficient of discharge.

As to the factors that influence the quantity of flow through an orifice, the following are listed as the most important:

1 Initial pressure of air supply, and in some cases the ratio of the back to the initial pressure.

2 The shape of the orifice, whether it is cylindrical, conical, of convergent or divergent type, or a combination of the two. The length, or rather the ratio of diameter to length, or if an orifice in a thin plate, whether it is bevel- or straight-edged.

3 The condition of the interior surface—smoothness. And also whether the entrance is well rounded and free from sharp breaks in outline of the nozzle curve.

It appears that the coefficient increases with the initial pressure and also with the ratio of back to initial pressure, and that a short orifice with well-rounded approaches will give a coefficient of discharge of approximately 0.98.

Another important factor brought out is that since the time of Zeuner and Fliegner's experiments it has been well established that when the ratio of the final pressure P_2 to the initial pressure P_1 has a value of 0.527, the discharge is a maximum: and for all values $P_2 < 0.527\ P_1$ the discharge remains a constant maximum value. It is well to note, though, that in the case of orifices in thin plates, W (see notation below) appears to keep on increasing after the pressure becomes lower than 0.527 P_1, although the increment of increase has a decreasing value as zero is approached and is very much less than the increment from P_1 to the critical pressure.

Now if

W=weight of air discharged per sec.

A=throat area of orifice in sq. ft.

P_1, P = pressures inside and outside orifice in lb. per sq. ft.

n = ratio of specific heats = 1.404

T = absolute temperature at P

V = volume in cu. ft. at P

the weight of gas discharged in unit time for frictionless adiabatic flow is

When $T = 460 \quad 60$

$n = 1.404$

$$r = \frac{P_2}{P_1}$$

P = pounds per square inch.

$$W = 0.07058\ d^2\ P_1\ n \sqrt{r^{1.425} - r^{1.712}}$$

and the best values of the discharge coefficients as shown by this review are as follows:

For Orifices in Thin Plates (Straight-Edged):

Low pressures (1-12 in. water) . . . . $\mu = 0.60$

Medium pressures (15-50 lb.) . . . . $\mu = 0.63$

High pressures (50-150 lb.) . . . . $\mu = 0.65$

For Nozzles:

Short cylindrical . . . . $\mu = 0.75$

Short, well rounded, convergent . . . . $\mu = 0.98$

Convergent 6°-10° . . . . $\mu = 0.90$

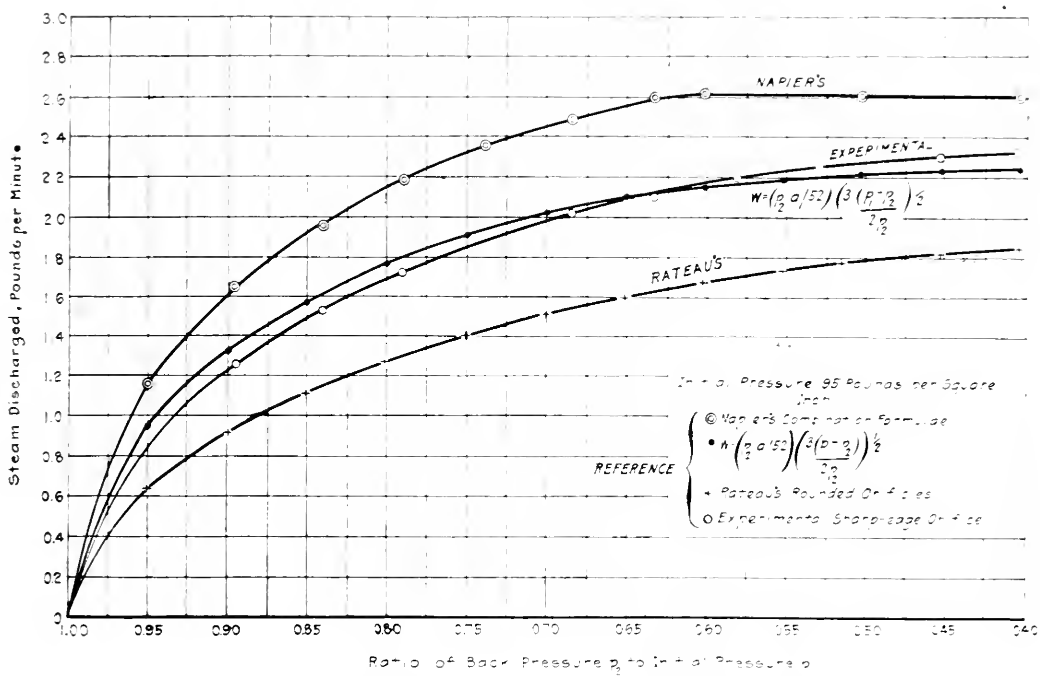

Fig. 2 Comparison of Formulae for Flow of Steam through Orifices

As regards the investigation on needle nozzles, the writers had before them the problem of designing a needle-nozzle control of air discharge from a turbo-compressor set that would meet the following requirements:

1 To deliver 30 hp. at 3400 r.p.m., that is, 2500 cu. ft. of air at 60 deg. fahr. and 14.7 lb. barometric pressure, having a delivery pressure of 2 lb.

2 Of such shape of needle that the issuing core stream from the nozzle could in any position of the former be explored as to cross-section, velocity, and pressure conditions existing in it.

Thus the problem resolved itself into two divisions, the design of the nozzle proper and the design of the needle. An

adiabatic formula for frictionless flow was adopted as the basis of design.

The needle was designed by using a combination of curves that would give in outline one similar to the present water nozzle needles and of such shape as to offer small resistance to flow. It soon appeared, however, that while this would satisfy conditions for full load, in going from this output to no output the needle would be so located that the velocity from initial to final point would have a decreasing increment at most positions. This was due to the fact that the area between the nozzle and the needle at the inlet was less than the net area of the outlet. Thus it became necessary to adopt a design which in any position of the needle would give such a succession of areas between the nozzle and the needle from the entrance to the outlet, that the velocity would have an increasing increment in traveling this distance and that as nearly as possible the flow would approach the frictionless adiabatic as an ideal.

The following plan was followed: The nozzle was designed for full load, and then a series of areas determined that would give $^3/_4$, $^1/_2$, and $^1/_4$ loads, respectively. The next step was to so lay out the needle that at these different positions the effective area—the difference between the nozzle's and the needle's areas—would be a series that would fulfill the flow and load requirements for that position. This was done by shifting

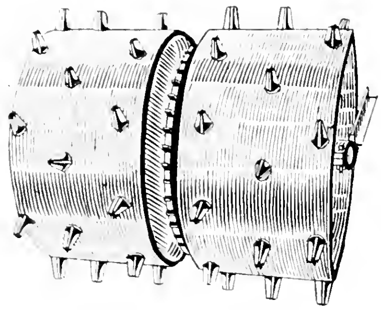

Fig. 3 The Rear Wheels of the Whiting-Standard Tractor

along a vertical axis the superimposed curves (different curves) and then drawing an averaging curve through them.

The area to be obstructed by the needle at different loads is the annular area between the full-load adiabatic and the adiabatic for the given load. The needle difference curves are plotted by radii, which radii are the radii of circles whose areas are those of the annular rings.

From the first part of this report one of the main conclusions of the investigation in regard to the flow of air through orifices was to the effect that a well-rounded short nozzle had as the highest coefficient of discharge the value of 0.98. Therefore a short nozzle designed by the adiabatic formula, following this type and using a needle whose shape was determined as previously stated, may be expected to have a high degree of flow efficiency. This remains for experimental determination.

In connection with the above investigation, a series of tests was run to determine by actual measurement the rate of discharge of steam through a sharp-edged orifice 0.203 in. in diameter and in a 0.125-in.-thick brass plate.

In the computation of the rate of discharge, the authors used Grashof's formula. The results of the tests are shown in Fig. 2, where the curve obtained in the present experiments is compared with those of Napier and Rateau. (*Thesis presented to the Department of Mechanical Engineering, Leland Stanford Jr. University*, 1916, *et*)

Automobiles

Whiting-Standard Farm Tractor

The essential feature of this tractor is the employment, instead of the usual driving wheels, of two broad-treaded rollers (3 ft. 9 in. diameter) which together make up considerably more than 4 ft. There is no differential on the shaft to which both rollers are keyed (Fig. 3) and by which both are driven. The drive is effected through a single strong chain from a simple form of gearing, with one speed forward and one backward.

With such an arrangement it would be very undesirable to have one roller on the land and the other in the furrow, and therefore when plowing the plow is hitched on so as to come well to the side.

The two front wheels are quite close together. In the steering gear a small bevel pinion on the end of the steering column turns the bevel pinion mounted on a vertical shaft. In addition to this another small bevel pinion mounted on the same vertical shaft as the bevel wheel is in mesh with a large-radius tooth quadrant keyed to the central column which forms the pivot upon which the short front axle turns. This multiplies the mechanical advantage of the bevel several times. With this gear the machine can be turned in a circle of 30 ft. diameter; in other words, on a 15 ft. headland. (*Motor Traction*, vol. 24, no. 620, January 17, 1917, pp. 41-42, 4 figs., *d*)

Truck-Spring Lubrication

The Fageol truck, made by the Fageol Motor Company of Oakland, Cal., has a unique system of spring lubrication, shown in Fig. 4. The upper view shows the support for the rear end of the front spring. The frame bracket is hollow and can be filled with oil. A wick leads from the reservoir to the center of the upper shackle bolt. This is drilled out and bored with a cross-hole, allowing the oil to pass to the left-hand end, whence it goes down through a hole in the side of the shackle to the lower bolt, which is also drilled to carry the lubrication to the middle of the bushings.

The lower view shows the suspension for the front end of the rear springs, the section being a projection on the center line of the filler cap. At the bottom is the rear-end hanger for the rear spring, in which the wick lifts the oil from the reservoir to the upper bolt.

It is not stated how often the oil is to be replenished in the reservoirs, but this operation would not have to be performed except at fairly long intervals. (*The Automobile*, vol. 36, no 3, January 18, 1917, p. 185 illustr. *d*)

Conveying Machinery

Belt-Conveyor Coal-Loading Plant in New South Wales.

Description of a large belt-conveyor coal-loading plant recently erected at Port Kembla, N. S. W., under the direction of the Department of Public Works of New South Wales.

The port of Kembla was designed to accommodate ocean-going ships. On the completion of the port the breakwaters will include an area of 335 acres, with an entrance 1000 ft. wide. The depth of water at the entrance will be 49 ft. and on the coaling jetty 25 to 34 ft. at low water. The distance

from the railway along which the coal arrives to the 25-ft. low-water-depth line is 355 ft., and it was decided to build a jetty at right angles to the shore and equip it with a belt-conveying plant.

Siding accommodation is provided at the shore end of the jetty for 500 trucks. The full cars approach the shore end of the jetty on an incline of 1 in 120, and when empty proceed via the remainder of the loop to the empty sidings. Although the feeding loop as it approaches the jetty is on an incline, it is found advisable to have the trucks coupled and controlled by a shunting engine when unloading, as by this method the trucks are more readily handled than if gravitated, owing to the time lost in stopping and starting. At the point of intersection of the feeder lines and jetty, and under the former, is

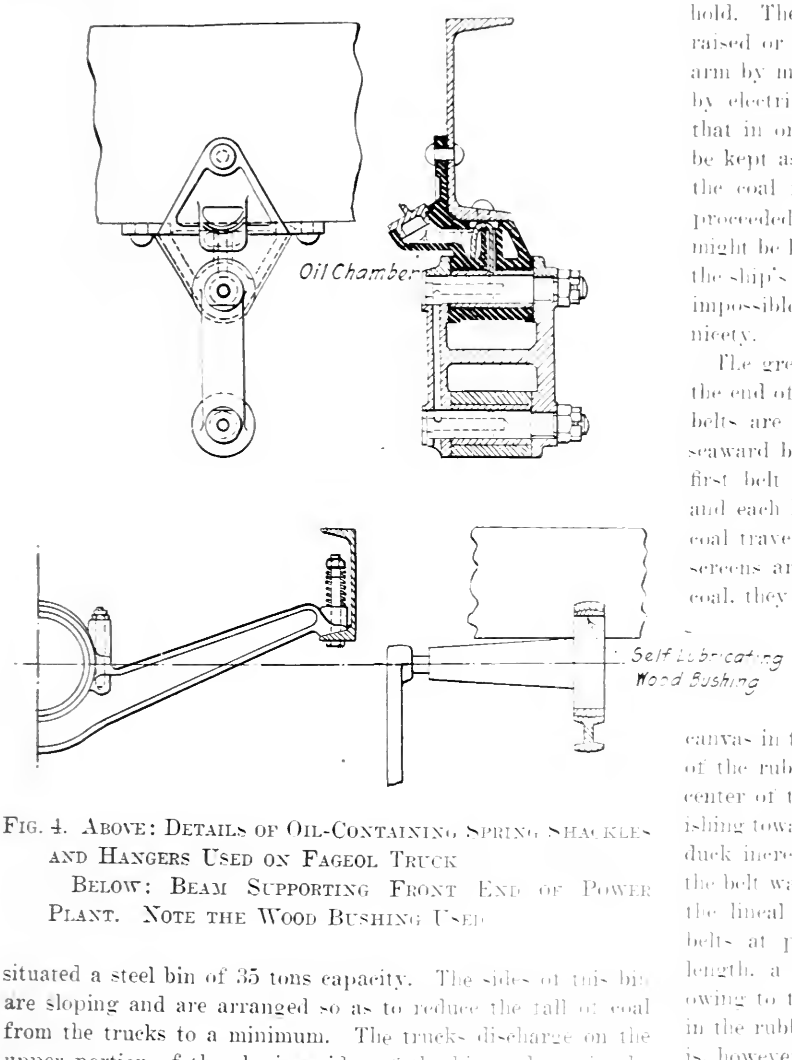

Fig. 4. Above: Details of Oil-Containing Spring Shackles and Hangers Used on Fageol Truck
Below: Beam Supporting Front End of Power Plant. Note the Wood Bushing Used

situated a steel bin of 35 tons capacity. The sides of this bin are sloping and are arranged so as to reduce the fall of coal from the trucks to a minimum. The trucks discharge on the upper portion of the sloping sides of the bin and not in the center, which minimizes the free drop of the coal and consequent breakage.

Because of lack of space, only the more unusual features of the design will be here reported.

The deck of the jetty is 8 ft. above high water of spring tides. The main conveyor belt is carried 3 ft. above the deck level of the jetty for 480 ft. from the shore, and at 580 ft. a driving station is constructed and the first section of belting ends. From this point the belt rises on a gradient of 1 in 5.5 on a light structure for a distance of 105 ft., and is continued on that level 22 ft. above the deck to the end of the jetty. While the jetty itself is of substantial construction, the framework carrying the main belts is of far lighter construction than would be necessary if trucks and locomotives were to be carried, and the gradients are much steeper than would have been practicable for loaded trucks. The fact that the coal can be lifted to the necessary elevation on this comparatively light structure is an important point in favor of economy in first cost of the plant as compared with an ordinary high level jetty designed to carry trucks and locomotives. The further fact that the shore end of the jetty for a length of 531 ft. is only 18 ft. in width is also an economical feature in its construction, as, were it necessary to handle trucks on the jetty, a wider construction would have been necessary throughout. Each of the traveling arms is equipped with a conveyor belt which discharges the coal into a rectangular chute 3 ft. x 3 ft. x 34 ft. long, hung vertically between jaw ends at the end of the arm. Through this chute or loader the coal descends into the ship's hold. The loader has lateral play, and in addition can also be raised or lowered independently of the position of the loader arm by means of side pulleys moving in guides and operated by electric motor. The original intention in the design was that in order to minimize breakage of coal the loader should be kept as low as possible, indeed, practically in contact with the coal in the vessel, and be slowly raised as the loading proceeded. It was thought that in this manner the chute might be kept practically full of coal and actual dropping into the ship's hold be obviated. In practice, however, it was found impossible to regulate the operation of the chute with such nicety.

The great length (1400 ft.) from the flight-conveyor pit to the end of the jetty precluded the use of a single belt, and two belts are used. The short belt is 698 ft. in length, and the seaward belt 722 ft. between centers of tension pulleys. The first belt discharges onto the second over a gridiron chute, and each belt is operated at the forward or seaward end, the coal traveling toward the operating pulley. Although timber screens are provided on each side of the belt to protect the coal, they are not close enough to the belt to act as guides to keep the coal in place, nor are any such guides necessary, the troughing of the belt sufficing for that purpose.

The belts are 36 in. in width, with four-ply duck canvas in the center and seven-ply at the edges. The thickness of the rubber coating is $\frac{1}{16}$ in. on the back and $\frac{3}{16}$ in. in the center of the working face, the thickness of the rubber diminishing toward the edges of the belt as the number of the plies of duck increases. The canvas duck used in the manufacture of the belt was specified to withstand a tensile stress of 400 lb. on the lineal inch after vulcanizing. Each of the four rubber belts at present in use was manufactured in a continuous length, a course which was thought advisable at the time owing to the great difficulty of providing a satisfactory joint in the rubber belting. Mr. de Burgh, who designed the works, is, however, satisfied that this construction is not to be recommended. The task of getting the long belts into place, which necessitated the unshipping of the idlers and pulleys, was a very serious one, and the danger of a complete and prolonged interruption of the working of the plant following an accident to a portion of the belt is so great as to make it most desirable that jointed belts should be used. However, one of the loading-arm belts needing repairs has been cut out and a new belt jointed with so-called alligator steel clips has been introduced. If it proves satisfactory the like can be used in the main belts if required.

These rubber belts have been in operation since April 1915, and had up till the beginning of September last loaded 231,514 tons of coal and 47,635 tons of coke, and their condi-

tion was then excellent. Not only were immense lumps of coal delivered from the collieries, but pieces of broken machinery and even sleepers with dog spikes protruding from them came through the chutes. No serious damage, however, resulted from these causes, and, while small abrasions of the surface of the belt occurred, it has not yet been necessary to cut out a length of the main belt. To make surface repairs cheaply and rapidly, a small portable vulcanizing plant has been provided.

The conveyor belts are operated at a speed of 360 ft. per min. This speed may be increased to 500 ft. per min. by a simple alteration of the gearing, but it has been found that the speed of the plant was sufficient, particularly as the speed of coaling is controlled by the trimming time of the vessels. In the case of one vessel, S. S. *Winfield*, 5420 tons were loaded in a total working time of 27 hr. 40 min., giving a loading speed of 196 tons per hour. The actual working time of the conveyor was, however, 11 hr. 32 min., or 58 per cent of the total time, and the quantity of coal loaded per hour of running time was 467 tons. While loading this vessel, 178 cars containing approximately 10 tons each were discharged, sent on to the empty roads, and the contents loaded in 182 min. running time. Further, during an uninterrupted run of one hour with a single chute discharging into one hatch, 500 tons were loaded, and in a similar run of one hour with two chutes working into two hatches, 647 tons were loaded, which is a very high rate for loading.

The whole plant is electrically operated. The total cost of the Port Kembla jetty coal-loading machinery and power house, including the concrete foundations of the latter, also of flight-conveyor pit and in the belt subways, but excluding all railway lines in approach, may be taken at £83,000. (Paper read by E. M. de Burgh before the *Northern Engineering Society of New South Wales*, September 13, 1916, abstracted from a report in *The Engineer*, vol. 123, no. 3184, January 5, 1917, pp. 5-8, 5 figs. *d*)

Corrosion

A Method for Practical Elimination of Corrosion in Hot-Water-Supply Pipe, F. N. Speller

Discussion of a method for " fixation " of oxygen and carbon dioxide in water previous to the latter entering the pipes, and description of two experimental plants and of results obtained.

Two methods may be used for removing from water gases producing corrosion. One is, reducing the pressure of the heated water, and the other, keeping the hot water in contact with a large surface of iron under pressure for a sufficient length of time to remove and fix the oxygen and carbon dioxide. The latter method has been in use at two plants during the past year: the research laboratory and hospital building of the National Tube Company, McKeesport, Pa., and the Irene Kaufmann Settlement, Pittsburgh, Pa. It is claimed that both installations have demonstrated that the corrosion of iron or steel pipe can be arrested and practically eliminated by this process.

The Irene Kaufmann Settlement was built in 1910, using wrought iron and steel pipe for the hot- and cold-water lines with storage tanks and gas heaters. All the hot-water piping was showing signs of serious corrosion by 1915 and a number of pieces had to be replaced with brass pipe. Every week or two replacements and repairs had to be made, which constituted a source of serious inconvenience.

The experimental plant which was put into use in December, 1915, consisted of a storage tank filled with alternate pieces of corrugated and plain steel sheets No. 26 gage, arranged radially around the filter. The water was heated by a heater with a capacity of 3 gal. per min., and passed downward between these plates, being thereby deoxidized to a large extent. The water then flowed upwards through pipes to the top of the filter and downwards again through the filter and finally up through the central pipe to the system.

It is of course necessary before use to filter the fine rust out of water so treated, and it is also necessary that the filter be so designed in connection with the heater as to be kept hot when no water is being drawn. An illustration shows the course of the water circulating between the heater and storage tank, and the arrangement by means of which the temperature of the filter is maintained the same as that of the water in the storage.

For use as deoxidizers disks of Cambridge metal lath were placed. Strips of this or other suitable form of sheet iron may be used provided they are spaced so as to fill the chamber and yet leave a cellular structure with openings not over $1/4$ or $3/8$ in. through which the water can freely circulate. Steel turnings cannot be used because they get packed tight after a while. Rust occupies a space several times that of metallic iron and this must be provided for.

The average oxygen content of the water at the Irene Kaufmann Settlement before treatment was about 8 cc. per liter, and after treatment 0.5 cc. per liter. Since the treatment was installed, for nearly a year there has been no trouble with the old piping, even though it was in very bad shape at the time of the installation of the new plant.

Numerous corrosion tests were run by the Pittsburgh Testing Laboratory. Among other things it was found that there is no practical difference between the best grades of so-called " genuine " wrought-iron and steel pipe under the conditions of the test. These experiments also indicated that the water which had been in contact with the plates in the deoxidizer still carried considerable gas in solution, but this gas consisted mainly of hydrogen and nitrogen; in fact, the hydrogen frequently ran as high as 20 per cent.

From gas analyses and oxygen determinations made from time to time, it has been found that the rate of removal of oxygen has not diminished with length of service. Plates which were removed from the McKeesport plant after eight months' service had a thick layer of rust over the surface, but the efficiency of the tank was even greater after use. (*Journal of the American Society of Heating and Ventilating Engineers*, vol. 23, no. 9, January 1917, pp. 149-160, 6 figs. *e*)

Drying

Drying in Industrial Plants, J. O. Ross

Discussion of the fundamental principles underlying the design of drying systems.

It is generally true that as much drying out of the water should be done mechanically as is possible, by such means as pressing the material or by removing the water in centrifugals, as mechanical drying is cheaper than drying by heat. On material which would not be retained by the shell of a centrifugal, or which is not adaptable to the filter press, mechanical drying may be done in the settling tank. This system is in general use in the starch industry in Europe. The solid matter is allowed to settle to the bottom, and the water removed from the tank. In this way sludge forms on the bottom

containing about 50 to 60 per cent water, which is afterwards completely dried out in the heat driers.

As regards artificial drying, the simplest type is the one using direct application of heat, such as evaporating kettles to heat the material and vaporize the water. The next consists in placing the material in a heated room and allowing it to dry as best it may.

The design of driers is most essentially affected by the consideration of whether the drier should handle the material continuously or in batches. A progressive drier in which material moves gradually or continuously either on trucks or conveyors offers many advantages in cost of labor and economy of heat, as is well exemplified in the tunnel method of drying bricks. In addition to its economy, however, this method presents several other advantages. The wet "green" brick encounters only air which is comparatively cool and moist and it does not receive a harsh, quick surface drying which is so injurious. Another advantage is that each cubic foot of air is in intimate contact with the material throughout the entire length of the tunnel and picks up much more water than if it merely struck it and bounced off into space as it ordinarily would in a room drier.

There are, however, many cases when a progressive drier has drawbacks. This happens,

1 When the material comes from the machine in batches:
2 When the variety of the material differs widely in drying requirements;
3 When the material requires different treatment than a gradual increase in temperature and decrease in humidity of the air.

As regards the third condition, its importance grows as more study is given to the drying problem from the standpoint of quality of material.

As regards "apartment" driers, one of the main troubles connected with their operation can be overcome by decreasing the capacity of the compartments and increasing their number. The greater the number of compartments, the more nearly does an apartment drier approach the efficiency of a progressive drier. In lumber mills making products varying from 1 in. thick to 4 in. thick, an apartment drier presents many advantages, even if it is necessary to put the different thicknesses of material in the same compartment.

As a general rule, material which dries fast is more adaptable to a progressive drier than a material which dries slowly. Indeed, in extreme cases where the material requires a long drying, it would be found that a progressive system would travel so slowly as to be troublesome.

The entire efficiency of the drier usually depends on how intimate the contact is between the air and the material. From this point of view, a progressive drier is probably several times as efficient as drying in a room by simply blowing in warm air.

A very common type of drier of the simple order is the so-called bed or screen type. This usually consists of a horizontal screen on which loose material is thrown. Air is applied under pressure to the under side of the screen and forced up through the material, which usually means a very intimate contact and a very high efficiency. This method is applied to the drying of grain, scrap rubber, wool, cotton, and similar materials.

The cylindrical drier gives a very intimate contact between the drying medium and the material to be dried. In the more common type this consists of a round cylinder, usually on an incline. The material is fed in at one end and as the cylinder revolves the material is thrown around in such a way that it presents a large amount of surface to the warm air which passes through the cylinder. Baffles and paddles are placed inside so as to aid in this throwing, and the incline should be made such that the material will travel at a fixed rate of speed through the cylinder.

In general, in designing a drying system, considerable study should be given to the material and the drier designed in such a way that the warm air will come into the most intimate contact possible with the material. It should be borne in mind that there is a certain limit to the speed of drying of all material, and this limit should be determined. The writer has known materials that would dry in 40 hours in a very crude drier, but, even when placed in a first-class drier, would not dry in less than 36 hours. This is the big problem that an engineer encounters on a drying proposition—as to how long he may expect it to take to dry, as this determines the highest speed possible in the movement of the material. (*Journal of the American Society of Heating and Ventilating Engineers*, vol. 23, no. 2, January 1917, pp. 201-207, *g*)

Engineering Materials

An Investigation of the Brittleness Produced in Steel Springs by Electroplating, M. DeKay Thompson and C. N. Richardson

Several years ago Dr. W. H. Whitney called attention to the fact that small steel springs become brittle when plated in a copper-cyanide bath. The writer undertook to find the cause of this deterioration and to establish under what conditions it does and does not occur.

While no explanation of the brittleness produced in a spring wire when used as a cathode in a hot cyanide solution could be found, results of considerable interest were, nevertheless, obtained. These results are summarized by the authors as follows:

1 Spring steel becomes britfle when used as cathode in a hot cyanide solution, either sodium cuprocyanide or simply sodium cyanide. The effect is more pronounced with the simple salt. Brass and phosphor bronze are not affected.

2 Brittleness was not produced by the liberation of hydrogen on the steel.

3 The carbon content is not changed by electrolysis.

4 The crystalline structure is not changed by electrolysis.

5 The brittleness is not produced in annealed wire.

6 The brittleness is produced by use as cathode whether the wire is coiled or not bent in any way.

7 The brittleness is not produced when the wire is used as anode or when it is suspended in the solution without the passage of electricity. (*Metallurgical and Chemical Engineering*, vol. 16, no. 2, January 15, 1916, pp. 83-84, *e*)

Cast Iron for Engine Cylinders, J. Edgar Hurst

The paper was divided into three sections, the first dealing with the wearing of cast iron, its structure, hardness and machining considerations. Section 2 was on growth and dealt with heat treatment of gray cast iron and the effect of heat treatment on engine pistons. Section 3 was devoted to the chemical constitution of the metal.

Under a given load and speed it would appear that wear in engine cylinders was proportional to the tensile strength of the iron. Cast iron of the highest tensile strength at normal temperatures was that having the closest-grained structure and the

free carbon constituent existing in a very finely divided or, alternatively, in a rosette form. In so far as pure surface disintegration was concerned, the identity of the micro constituents of cast iron is of little moment, but it becomes of importance in view of the effect of the action of alternating stresses on the character of the surface grains and the effect of the differential polishing of these grains.

With regard to hardness tests, the method of applying Brinell hardness numbers to cast iron in the case of engine cylinders is far from satisfactory. Cast irons giving the same hardness numerically often wore at widely different rates, and, furthermore, the influence of the presence of such elements as manganese and chromium, which in normal percentages were not detected by the hardness numeral, was most important.

There is a great amount of uncertainty in the definition of hardness and it is very doubtful whether the methods of determining hardness actually do determine this property in its entirety. The author states that in his opinion in a homogeneous material a true hardness property is its resistance to wear. From this, therefore, the resistance to wear becomes a function of the cohesion of the particles, or, rather, becomes the resistance to deformation, and therefore he suggests tentatively that the yield point is a more correct indication of the true hardness.

As regards cast iron, the author said it was extremely probable that wear due to surface disintegration was really a function of the brittleness of cast iron. The abrasion or relief polishing was the true wear, in that it depended upon the resistance to deformation of the individual component grains.

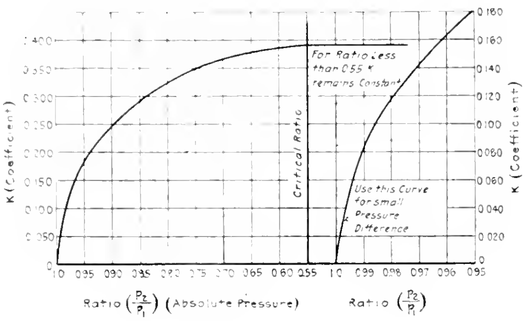

Fig. 5 Curve of K (coefficient) for Flow of Natural Gas Through Standard Orifices

The temperature at which growth appeared to commence was about 650 deg. cent. and it reached a maximum at about 750 deg. cent. After prolonged heating, in addition to a gradual increase in volume a gradual increase in weight was also noted. The facts are established that:

1. Alloys not containing graphite do not grow.
2. Alloys containing graphite are, under suitable conditions, capable of growing; and, further, the total growth is roughly proportional to the silicon content.

In this connection the author discussed piston troubles with Diesel engines. He believes that the ultimate cracking of Diesel-engine piston tops could as a general rule be traced to the phosphorus content of the cast iron, and the cracking was practically eliminated when this was kept sufficiently low. Specimens taken from the center of a star crack in a piston showed liquation of the phosphide eutectic. This would undoubtedly increase the magnitude of the internal strains and, in addition, at points in the region of the center this same eutectic would at these temperatures be dangerously near its liquation point. Both phosphorus and silicon had a profound influence on the swelling out of the graphite plates. (Paper read before the *Manchester Association of Engineers*, December 9, 1916, abstracted through *The Engineer*, vol. 122, no. 3182, December 22, 1916, pp. 549-550, 1 fig. *te*)

Gas Engineering

Measuring Gases by a Standard Orifice

Prof. Thomas G. Estep, Jr., of the Carnegie Institute of Technology, gave the following formula for weight of gases discharged through an orifice in pounds per second:

$$W = \frac{A P_1 K}{\sqrt{T_1}}$$

where A = area of orifice in square inches; P_1 = pressure just ahead of the orifice, pounds per second absolute; K = coefficient from curve for flow of air through standard orifice, Fig. 5; and T_1 = initial temperature of gas, degrees fahrenheit absolute.

For K the paper gives a rather involved formula. H. G. Geissinger, in his article in Blast Furnace and Steel Plant for February, 1917, offers simplified expressions for the constant K. He gives the following as a general formula for determining the value of K corresponding to value of d less than the maximum from the characteristics of the gas expressed by the values of R and n as

$$W = \frac{A P' K}{\sqrt{T}}$$

where W is discharge in pounds per second; A = net area orifice in square inches; P' = pressure on orifice, pounds per square inch absolute; d, drop in pressure across orifice, pounds per square inch; T = absolute temperature of entering gas in degrees fahrenheit; n = ratio of specific heats, constant pressure to constant volume; R = a constant for the gas in question. As an example of the use of this formula, H. G. Geissinger offers the following:

Determine K for a drop ratio of d = 0.25 (pressure ratio 0.75), in natural gas, where n = 1.27 and R = 4. From this data we find:

$$r = \frac{64.3}{94} = 0.683$$

$$f = 1 - \frac{(1.4 - 1.27)}{10} = 1 - 0.013 = 0.987$$

$$\text{and } p = 0.55 + \frac{0.72}{1.27} = 0.55 + 0.565 = 1.115$$

Therefore,

$$K = \sqrt{0.675\ (0.25 - (1.115 \times 0.0625)} = \sqrt{0.122} = 0.35$$

(Composite abstract of a paper by Prof. Thomas G. Estep, Jr., in *Blast Furnace and Steel Plant*, vol. 5, no. 1, January 1917, pp. 16-18 and 31, 2 figs; and paper by H. G. Geissinger in *Blast Furnace and Steel Plant*, vol. 5, no. 2, February, 1917, pp. 55-56. *et*)

A Method of Determining the Density of Flue Gases, Jas. Alex. Smith

It is often desirable to ascertain the density of a gas without making a chemical analysis. In the present paper the writer describes a novel method for determining gas density by gage reading.

The basic theory on which this method is founded is that the densities of gases and their pressures per unit of area of bases are directly proportional when the gas columns are of equal height. Hence if a column of air in a vertical tube

of known height is displaced by a given gas, the barometric and thermometric conditions remaining constant, the densities are in the simple ratio

$$D = \frac{P \pm P'}{P}$$

where D = density of the given gas referred to air taken as unity; P = known air pressure due to column height; P' = difference ($\pm$) of pressure due to gaseous displacement.

In his apparatus shown in Fig. 6, the writer shows a two-liquid differential gage which he has previously described in another article. The gas tube is simply a piece of 1/8-in. wrought-iron gas barrel A, 100 in. in height. At the bottom two stopcocks, B and C, permit alternate connection to a gas source or to the gage E. To check diffusion, the passage through the latter cock should be reduced to a pinhole. At the top a third cock, D, opening into the air, permits the tube to be gas-flushed and filled, and when the main passage is closed, continues the connection by a minute by-pass large enough to preclude any possible barometric difference of pressure between the gas inside and the air outside the tube, yet so small that the diffusion is negligibly slow. The surface of the liquid in the gage system and the bottom of the gas tube must be approximately at the same level.

The writer describes the method of calibration and the required corrections. (*The Mechanical Engineer*, vol. 38, no. 988, December 29, 1916, pp 509-510, 1 fig., *d*)

Machine Shop

Gas-Heated and Oil-Furnace-Heated Rivets, William F. Croston

Though the fuel costs are greater and the time of run longer, the Newport News Shipbuilding & Dry Dock Company prefers the gas furnace for heating rivets over the oil-fired type formerly used.

A test was recently run to check the cost of operating by gas as against the oil furnace formerly in use. Four hundred pounds of rivets were heated in each furnace. These were heated by the oil furnace in 44 min. and by the gas furnace in 57 min. The cost of heating the rivets by oil, with oil at 6 cents per gal., was 52.5 cents. The cost of heating a similar amount of rivets in a gas furnace, with gas at 55 cents, was 53.6 cents.

The rivets heated in the gas furnace were far superior to those heated in the oil furnace, as there was practically no scale on them, while the oil-heated rivets in same cases were badly scaled.

It is claimed that the gas-heated rivets stay hot enough to drive longer than those heated in the oil furnace, which is explained by the fact that the gas-heated rivets are heated evenly all the way through, while those heated in the oil furnace are extremely hot on the outside but not hot in the center, and thus cool more quickly than the gas-heated rivets. (*Bulletin of the Southern Gas Association*, January 1917, abstracted through the *American Gas Engineering Journal*, vol. 106, no. 4/3072, January 20, 1917, p. 87, 1 fig., *de*.)

Pumps

Motor Drive of Hydraulic-Elevator Pumps, Charles J. Carlsen

Data on the use of electric power for operating elevator pumps in important Chicago buildings and in particular in Hillman's Department Store, covering a period of three years.

The building was provided with 13 elevators, nine being hydraulic passenger elevators in two banks, four in one and five in another, and four steam elevators, two for passenger service and two for freight.

The hydraulic elevators are provided with vertical cylinders and plunger equipment 13 in. in diameter and 30 ft. long, with a maximum lift of about 80 ft. and a speed of about 400 ft. per min.; cars are operated on about one-half minute schedule; maximum pressure on the hydraulic system is 160 lb.

The steam equipment used for operating elevators was a 14 x 22-in., 14 x 20-in. Burnham simplex compound pump; a 14 x 20-in., 9 x 18-in. duplex compound pump, and a 16 x 9 x 18-in. duplex simple pump. On test, these combined pumps as operated consumed from 120 to 160 lb. of steam per i.hp-hr.

In September, 1913, a contract was entered into for supplying steam to the adjacent Reliance Building for the operation of various steam-driven devices. The amount supplied under this contract reached about 25,000,000 lb. of steam per year, as measured by a St. John meter.

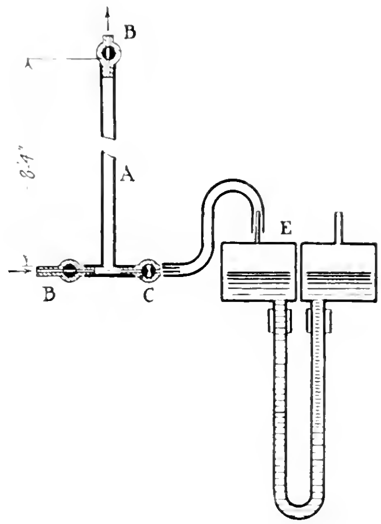

Fig. 6 Two-Liquid Differential Gage

All condensation excepting hot-water requirements is wasted to the sewer, there being no means provided for delivering these returns to the hot well of the boiler plant.

The bare cost for steam production per 1000 lb. based on a year's average and including only coal, ash removal, water for making and boiler compound, but not including any labor, maintenance or repairs, or overhead investments on plant, was found to be 24 cents per 1000 lb. with coal at \$2.85 to \$3.05 per ton. The writer gives the following figures to show the saving which he claims would be due to electric operation (Table 1).

This table is based on the assumption that a steam pump in fairly good condition will consume 120 lb. of steam per i.hp-hr., which is equivalent to 160 lb. per kw-hr.

In another office building, the Western Union Telegraph Building in Chicago, there was installed an equipment similar to that in the Hillman store, but using three three-stage, 350-gal.-per-min. Chicago Pump Company's turbine pumps, each direct-connected on a common subbase to a General Electric motor, and each controlled by a Cutler-Hammer control panel. Here the steam pumps are operated during the winter months

TABLE 1 HYDRAULIC ELEVATOR OPERATION, SUMMER MONTHS

	1913	1914	1915
Estimated Steam Operation Cost	$4,732.03	6,094.08	5,575.30
Actual Electrical Operation Cost	1,523.90	1,731.40	1,652.36
Annual Saving due to Electric Operation	$3,208.13	1,362.68	3,922.94

when exhaust steam is used for heating, but during the summer months the entire boiler plant is shut down and only a small boiler is run, of sufficient capacity to serve the building with the necessary hot water requirements.

The article briefly mentions also other buildings in Chicago, St. Louis and New York City using motor-driven pumps in the operation of their hydraulic elevators. (*Electrical Review and Western Electrician*, vol. 69, no. 25, December 16, 1916, pp. 1046-1049, 4 figs. *eg*)

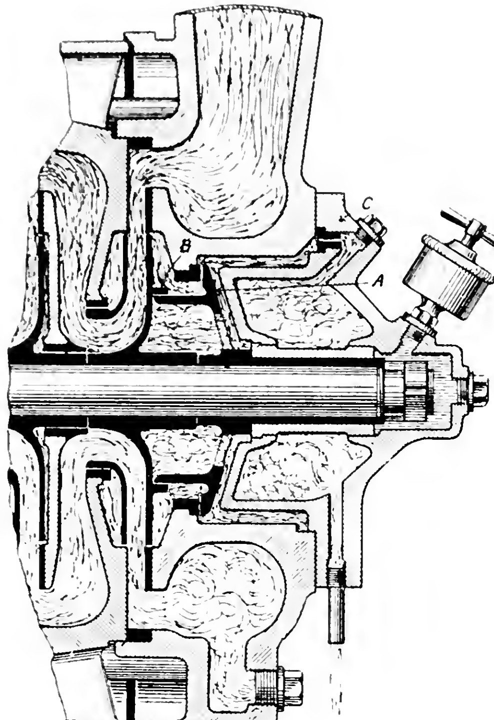

Fig. 7 Automatic Hydraulic Balancing Arrangement for High-Lift Centrifugal Pump

High-Lift Centrifugal Pump

Description of a centrifugal high-lift pumping set recently built in England for delivering 200 gal. of water per min. against a total head of 1250 ft.

In designing the set the makers were restricted to the use of direct current for the electric-motor drive. Hence the speed of rotation was limited and the number of stages in the pump correspondingly increased. The difficulty was overcome by arranging two four-stage pumps in line and driving them by a common motor which runs at 1400 r.p.m.

The pumps work in series, each giving a head of 625 ft. The automatic hydraulic balancing arrangement shown in Fig. 7 enables the makers to dispense with thrust bearings. This is effected in the following manner: A valve *A* carried from the shaft by means of arms is so constructed that it fits into a ring *B* on the delivery side of the last impeller. The diameter of the ring is such that were there no hydraulic pressure on its inner area there would be an axial thrust towards the delivery end of the pump. The load necessary to balance the thrust on the impellers is taken on the back of the last impeller itself, as this forms one wall of the balancing chamber. The water required for balancing passes from the periphery of the last impeller to the balancing valve and thence to the balancing chamber, the outlet from which is controlled by the fixed orifice *B*. The latter connects with a drain. (*The Engineer*, vol. 122, no. 3182, December 22, 1916, p. 560, 2 figs., *d*.)

Railroad Engineering

Experimental Refrigerator Cars, Pennsylvania Railroad

The Pennsylvania Railroad has recently built at its Altoona shops two refrigerator cars to be used experimentally in milk-train service. The cars are essentially of all-steel construction.

In the design of these cars it was intended to utilize every means available, regardless of past practice, to provide a car that would furnish and maintain adequate refrigeration for milk and cream, either with ice placed in the ice bunkers or placed on top of the cans or boxes. Past experience indicated certain basic requirements enumerated in the original article.

The cars have trucks of special construction. The side frames are of cast steel. The side-frame center opening, the spring plank, and the wheelbase of 5 ft. 10 in. are the same as in freight trucks. The elliptical springs and bolster are the same as used on tenders. The axles are of the passenger type and the wheels are rolled steel, 33 in. in diameter. The journal boxes are pedestal-type passenger-car boxes. The truck, except for the bolster side motion, represents, therefore, a combination of passenger- and freight-truck features.

The end frame also combines passenger and freight principles. On the end sills and crossbearers oak blocks are placed to support the steel box forming the inside lining. The spaces between these blocks are filled with insulation consisting of four layers of 3/4-in. Keystone hair felt, separated by wooden grids to form air spaces.

The inside lining consists of 3/16-in. floor plates, 1/8-in. side sheets and 3/32-in. ceiling sheets, all reinforced with U-shaped braces riveted to the outside. It forms a box which can be built up complete on the floor and then lifted to its proper location on the oak supports. A 3/4-in. Keystone hair felt of as great width as can conveniently be manufactured and cut to the proper length is then lifted to the top of the lining box and unrolled to drop down the sides to meet and join the insulation under the floor. A continuous blanket is thus formed all around the inside box. There are four such blankets running transversely, separated with grids made of 1/2-in. strips of soft wood. Two additional layers separated with wooden grids are placed longitudinally on the top of the box and four layers are placed at the car ends to correspond with the sides. The Keystone hair felt consists of 1/4-in. hair felt placed between two sheets of 90-lb.-specification paper and securely sewed together.

The sides, ends, and roof are also reinforced with U-shaped braces and are so designed that the riveting can all be done from the outside. This also permits removing a side, end, or roof for repairs without thereby disturbing any other part of the car.

No data are given as to the results obtained with these cars. (*Railway Review*, vol. 60, no. 5, February 3, 1917, pp. 155-157, 8 figs. *d*)

Refrigeration

Refrigeration and Refrigerator Insulation on Board Ship. Robert F. Massa

Paper discusses the construction and insulation of refrigerators "built in" on board ship.

Difficulty has been encountered with the use of cork that had not been sufficiently pressed previous to baking. This cork was not as dense as it should have been, and had not the mechanical strength it should have had.

As to refrigerator doors, the idea seems to prevail that they should have beveled edges and that such edges make a very tight door. The writer claims, however, that as soon as the moisture begins to have its effect, such a door cannot be tight any more. Further, if the hinges yield at all, as they are likely to do with such a heavy door, it will never be tight.

In the writer's opinion, the way to make a tight refrigerator door is to have a plain surface come up against a plain surface with a flexible gasket between them, or two pairs of such surfaces with gaskets between them, making an air pocket between the two sills. If this arrangement is used the door can sag considerably without causing any serious binding or failure in tightness.

As regards estimating the capacity of the refrigerating machine required to take care of the given refrigerator, it is not sufficient to calculate on heat loss through the insulation of the refrigerator, as it is only a part of the total loss. The other losses are due to heat entering in warm goods, by the interchange of air through the opening of doors, and by leaks through defective insulation or defective doors; to lights, or to the heat of the bodies of workers; to any change of state occurring in the goods, such as freezing, fermenting, etc. (Paper read at the Annual Meeting of the Society of Naval Architects and Marine Engineers, November 1916, abstracted from *International Marine Engineering*, vol. 21, no. 12, December 1916, pp. 546-547. *p*)

Steam Engineering

Forced Lubrication for Marine Turbines

With the more or less general adoption of geared turbines on all classes of ocean-going vessels, in most of which, unlike the Navy, there are only two engineers on watch, it has become necessary to give the subject of lubrication considerable thought with a view to obtaining a degree of simplicity and dependability which will reduce attention to a minimum. As every trade route has its own conditions, it is impossible to devise a system suitable for every class of ship, but the following system is claimed to meet the requirements of many single-screw cargo-carrying vessels in the ordinary trade routes.

A combined gravity and forced system offers the greatest advantages and consists simply of a pump taking oil from a drain tank and discharging it through a cooler to a gravity tank, from which it falls to the turbine bearings, etc., and back to the drain tank; or it can be by-passed, in which case it does not enter the gravity tank but is forced direct to the machinery.

The following main fittings would be required for such a system, and are stated in the order in which the oil would pass through them when traveling from the drain tank to the turbines: one drain tank; two oil strainers (one for each pump); two pumps, one working and one stand-by; one oil cooler; two gravity tanks; one combined oil distributor and water-and-sludge collector.

The drain tank should be of sufficient capacity when full to supply oil for fifteen minutes, assuming that none is returning to the drain tank. It should be a self-contained unit placed in a cofferdam in the double bottom rather than built into it, and should be easy of removal for examination. The top should be not less than six inches below the bottom of the gear case to insure a ready drain, and not less than three inches above the double-bottom tank to clear bilge water. In addition to the drain- and suction-pipe connections a float-level indicator can be fitted so as to be easily observed from the starting platform, also an air pipe and manhole.

The body of the oil strainer may be of cast iron, having a cover easy of removal. The straining grid may be a gun-metal casting or a steel tube perforated with holes, say, one inch in diameter, but in either case the area through the grid should be about ten times that of the suction pipe. A suitable straining medium is a 24-mesh wire gauze, which should be properly secured to the grid. The gauze will, however, reduce the effective area through the grid by about one-half.

The oil cooler may take the same form as a steam condenser, with similar tubes and packing, but with the water circulating around the outside of the tubes with preferably a four or six flow to insure good circulation. As, however, it is economically impossible to render the flow of oil turbulent, which makes the rate of heat transfer low, certain firms construct their coolers in a different way. The water is passed through the tubes, and the oil outside. Numerous baffles are fitted to cause the oil to flow up and down in zigzag fashion across the cooling tubes, and at each abrupt change in direction a certain disturbance is produced in the laminar flow of the oil, which facilitates the interchange of heat. At present, knowledge of oil coolers is in its infancy and there is much room for research and careful design. The present practice admits of oil discharging to turbines at 80 deg. fahr. and leaving them at a maximum of 120 deg. fahr.

The combined oil lubricator and water-and-sludge collector need be nothing more than a cylindrical casting of sufficient depth to admit of water and sludge gathering at the bottom while oil flows out at the top to the bearings and gear sprayers. It is desirable to fit separate connections from the distributor to the bearings and gear sprayers with a controlling valve at each, which facilitates adjustments whereby bearings and sprayers will each receive their proper share of the oil. A water draw-off cock placed about twelve inches from the bottom and a door for removal of sludge are to be provided.

The turbine pipes and fittings should be tested to 50 lb. per sq. in., with the exception of the tanks, for which a 5-lb. test is sufficient. A relief valve should be provided near the pump, set to blow off at 50 lb. per sq. in. and having an outlet led to the pump suction. (*Engineering*, vol. 103, no. 2662, January 5, 1917, p. 12, Editorial, *dp*)

Doust Joints

The Doust patent expansion joint (made in England) is entirely telescopic in its action and has neither gland, packing, nor rings. It has been standardized by the Board of Trade for steam working pressures up to 215 lb. per sq. in. and is approved by Lloyd's. It has two outer shells and two inner liners with flanges on the ends; bolts pass through the flanges of the pipes. With any alteration of length of range of pipes due to expansion or contraction they are free to work telescopically.

In addition to the original Doust joint which has four sleeves, a new joint has been developed with three sleeves

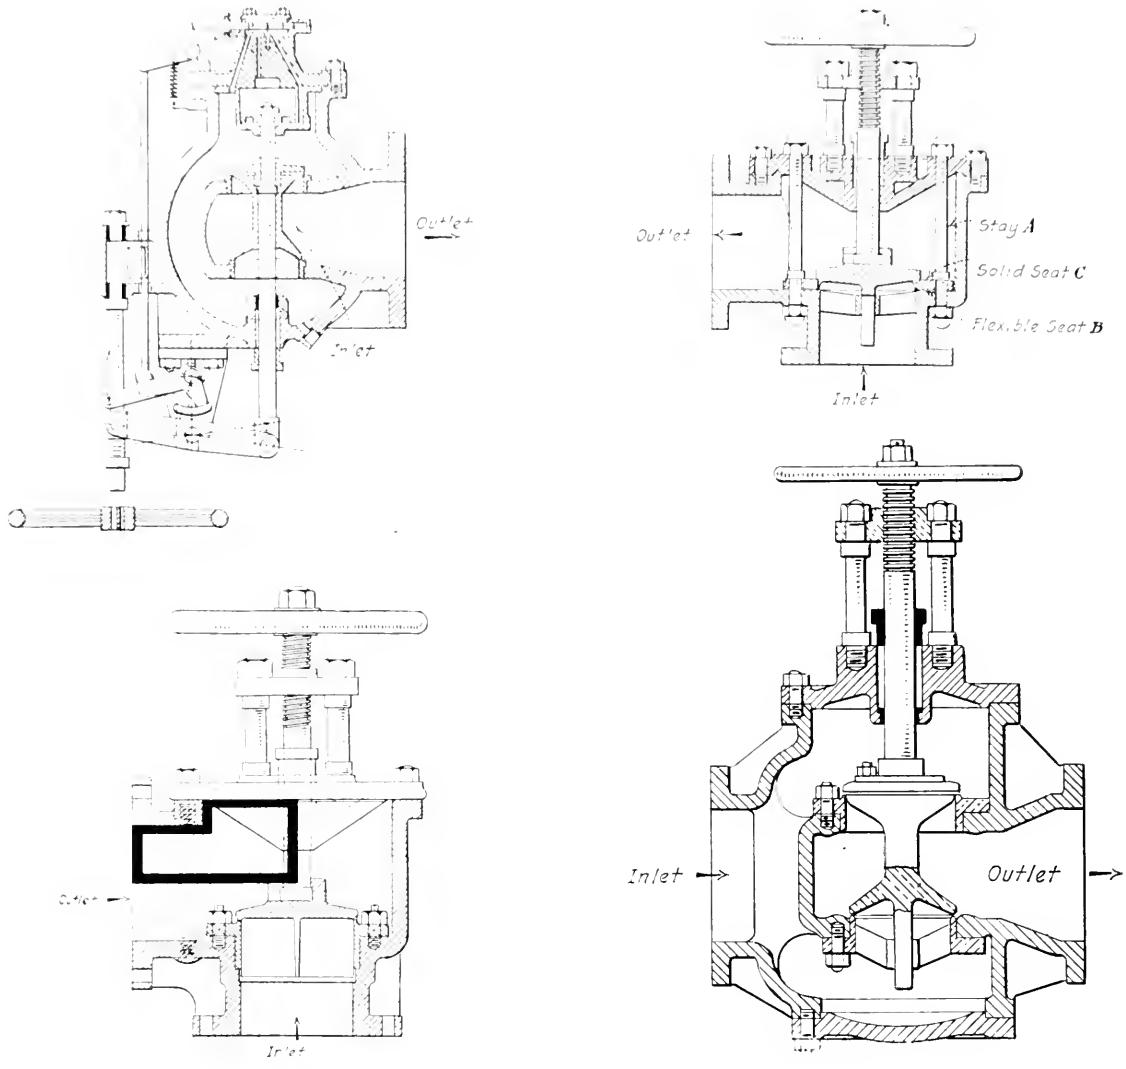
and is now under test to establish its suitability for steam. (*Steamship*, vol. 28, no. 331, January 1917, pp. 147-148, 2 figs. *d*)

The Design and Construction of High Pressure Steam Stop Valves, D. Macnicoll

Description of the essentials of design and sources of trouble in high pressure steam stop valves.

Fig. 9 shows a type of single-beat unbalanced stop valve frequently used as a boiler stop. This is not a very good design, because of the unequal distribution of stresses. Assuming that the pressure is present throughout the chest and acting at right angles to the plane of section shown, the stress on the part marked *A* is much higher than on the other portions. The pressure on the portion outlined in black is approximately 8950 lb., which stresses the section on the top left-hand side to 1061 lb. per sq. in., whereas the average stress for the aggregate section is only 891 lb. It is true that the cover takes a portion of this stress, but this simply transfers the stress on to the studs and therefore does not improve the overall strength of the valve.

The stresses resulting from excessive hardening down are in many cases exceptionally high. In fact, if the valve lid did not give way in nearly every such case, there might be far more fatal accidents in this connection. In valves over 4 in. in diameter a flexible seating in conjunction with a solid face is of advantage, as with this arrangement leakage from distortion is obviated, and, in addition, there are two faces, so that if one is leaking from any cause outside of distortion, there is always the other one to fall back upon.



Figs. 8-11 8, Left Hand, Top: Modified Double-Beat Valve for Regulating Purposes in Reciprocating Work. 9, Left Hand, Bottom: Single-Beat Unbalanced Stop Valve Used as a Boiler Stop. 10, Right Hand, Top: An Improvement on the Last Type of Valve. 11, Right Hand, Bottom: Double-Beat-Type Experimental Valve

Another source of high stress is when the valve has been shut down hard when cold and afterwards steam from other boilers is admitted to top portion of body. An actual experience of the author is illustrated in Fig. 10. This was a double-beat type of valve and the bottom seat was attached as shown. The valve was hardened down for steam test, with the result that after the test a number of manganese-bronze studs from the bottom seat were found lying broken in the bottom of the chest, and all showed signs of fracture caused by the expan-

sion of the spindle. One method of counteracting the damage from expansion is by fitting a spring crosshead. In Fig. 9 stays are sometimes fitted as indicated by the dotted lines. These only serve, however, to stiffen the cover and still further reduce the section of metal at an already weak section.

The rotation of the winged valves when steam is flowing is due either to a slight angle of the wings or to eddies in the steam. The valve can be prevented from rotating by means of a pin or otherwise. The damage done to valves from this rotation is hardly credible, and calls for the adoption generally of pintle- or center-guided valves.

Another source of trouble is the fracture of seat-securing pins or studs. In large sizes generally and in all sizes when superheated steam is present, seats driven in and secured by side pins become quite slack and allow leakage to occur. The seats in larger sizes are therefore secured in the manner shown in Fig. 9. The only way to avoid serious trouble with this design is to run a wire through the heads of all pins or through split-pin holes if studs are fitted. This prevents fractured portions being carried to some part where serious damage may be caused.

In Fig. 10 a type of valve is shown which is suggested as an improvement on that shown in Fig. 1. Attention is drawn to the method employed with a view to having the cover take up a measure of the bursting pressure which acts at right angles to the axis of the spindle. This consists of a tapered spigot on the chest with a corresponding tapered recess in the cover, making a metal-to-metal joint. The stresses from hardening down and expansion are mainly taken up by the four stays *A*, which also serve to secure the seatings. With this arrangement no loose parts are situated inside the chest, with the consequent prevention of damage from this source. The valve is centrally guided, thus preventing rotation. A flexible seat is shown at *B*, and when this and the corresponding valve face engage, the solid seat *C* and its corresponding valve face are 1/100 in. open, so that when this latter seat and face engage, the flexible seat is deflected 1/100 in.

Next is described a flexible disk to one of the beats of the solid double-beat valve, the purpose of which is to prevent leakage due to differences of expansion between the valve and the seat in the chest.

As regards double-beat types of valve used in reciprocating work for regulating purposes and as throttle valves, the writer states that in the future it is intended to make valves of the type shown in Fig. 8. Here a constant closing effort is present and will allow of perfect regulation under all circumstances and will not necessitate the adoption of saw-formation spigots on the beats. The slide valve is returned from position III to positions II and I by a spring assisted by the inlet pressure on the area of the slide-valve spindle where it passes through its stuffing box. Special types of ahead and astern double-beat regulating valves for turbine and reciprocating machinery are shown and described. (Paper read before the *Institute of Marine Engineers,* December 12, 1916, abstracted through the *Mechanical Engineer,* vol. 39, nos. 989-990, January 5 & 12, 1917, pp. 8-9 and 20-22, 13 figs. *d.* The original paper is not available.)

Thermodynamics

Heat Density. George P. Pearce

We hear a great deal about the B.t.u. value of fuels, that is, the B.t.u.'s of potential chemical energy contained in 1 lb. of various substances, but how many have considered the number of B.t.u.'s of heat there are in a cubic foot of space under various conditions? Let us assume 0 deg. fahr. as a base and see approximately what the heat density is for various conditions and substances. On a hot summer day, with the thermometer registering 110 deg., there seems to be plenty of heat everywhere, yet a simple calculation will show that there is only 1.8 B.t.u. to the cubic foot.

The gasoline blast torch is generally looked upon as a very hot flame, but in the hottest part of that flame the heat density is less than expected; it is 10 B.t.u per cu. ft. Hydrogen gas, with its enormous heat value, might be expected to make a better record than that, yet in the hottest part of a hydrogen flame burned in the air the B.t.u.'s per cu. ft. are just about 10.1: it has a heat density 1 per cent better than the gasoline flame in air. Not much is expected of carbon burned in air with its much lower heat value, so we are surprised when it shows a density of 12.3 B.t.u. per cu. ft. This, of course, is due to the greater density of the products of combustion. Incidentally, we note why coal is such a satisfactory source of heat for boilers; it develops a high heat density and thus rapidly heats the tubes; of course, other things enter into consideration as well. A great deal is said about acetylene, and it deserves credit, for this gas burned in air produces a heat density of 13.1 B.t.u. per cu. ft. So far the heat produced has been diluted by the presence of the inert gas nitrogen in the air. Eliminate this and burn acetylene in oxygen and a great change takes place, for now there are 24 B.t.u. in every cubic foot of the intense flame. Burn hydrogen in oxygen and there are 20 B.t.u. to the cubic foot.

It might be supposed that the limits for heated gases and vapors are being rapidly reached. However, ordinary steam just as it boils off water into the atmosphere contains 44 B.t.u. to the cubic foot. The oxy-acetylene flame takes a poor second place when compared with steam under these conditions. Some experimental high-pressure, high-efficiency, steam engines use superheated steam at 240 lb. per sq. in. and 300 deg. of superheat, and every cubic foot of this steam contains over 500 B. t. u. Strange as it may seem, saturated high-pressure steam at 235 lb. per sq. in. contains over 650 B.t.u. per cu. ft., and for carrying heat is superior in this respect to superheated steam. More astounding still is the humble cake of ice, which at 32 deg. is prepared to deliver 937 B.t.u. per cu. ft. when cooled down to zero. Boiling water is common enough, and as a heat container it holds over 12,000 B.t.u. per cu. ft.

Melted sulphur at 800 deg. fahr. has a heat density about twice that of boiling water, or over 22,000 B.t.u. to the cubic foot. Melted aluminum at 1214 deg. fahr. almost doubles this, with nearly 43,000 B.t.u. per cu. ft. Melted glass at 2377 deg. fahr. has nearly 75,000 B.t.u. in every cubic foot. Platinum, at 3300 deg. fahr., makes a big jump with its 182,200 B.t.u. per cu. ft. But common melted iron, at 2700 deg. fahr., leaves platinum away behind with 207,000 B.t.u. per cu. ft. However, they are all surpassed if a cubic foot of carbon is heated almost to its vaporizing temperature, say to 7000 deg. fahr., as a heat density of 700,000 B.t.u. per cu. ft. is then obtained. It is impossible for a person to look at this heated carbon or stand near it, and probably it represents the greatest heat density known. It is found in every arc lamp. Perhaps, when we obtain more data on this remarkable metal tungsten, which takes 5432 deg. fahr. to melt it and an unknown temperature to vaporize it, a still greater heat density may be had in melted tungsten just before it commences vaporizing. The Determination of Free Energy by the Clausius Equation of State, E. Aries

For a body considered from the point of view of its molecular weight, the Clausius equation can be written as

$$P = \frac{RT}{v - \alpha} - \frac{\phi(T)}{(v + \beta)^2} \quad [1]$$

If the latter of the two constants is zero and the function ϕ is reduced to a constant K, the Van der Waals equation is obtained.

The above equation has a remarkable property which in the opinion of the author has not been perceived, in that it gives in a very simple manner an expression for the free energy I as a function of its usual variables, volume and temperature. We know that this energy expressed in this manner is one of the four Massieu functions, each of which is sufficient to determine all the properties of a body. We know that

$$-\left(\frac{\partial I}{\partial v}\right)_T = P = \frac{RT}{v - \alpha} - \frac{\phi(T)}{(v + \beta)^2} \ldots\ldots\ldots\ldots [2]$$

from which, by integration with respect to v, we obtain

$$-I = RT \log (v - \alpha) + \frac{\phi(T)}{v + \beta} - \Phi \ldots\ldots\ldots\ldots [3]$$

where Φ is a function of the temperature introduced by the integration and may be determined from the theory of perfect gases.

If we assume that the volume v progressively increases at constant temperature, the body tends toward the state of a perfect gas. α becomes finally neglible as compared with v, and the equation [3] is reduced to the following (which is the equation given by the theory of perfect gases):

$$-I = RT \log v - \Phi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [4]$$

From this equation may be derived the following expressions, first, for the entropy S, and next for the molecular heat capacity at constant volume c (which constant is the same for all perfect gases of the same molecular complexity):

$$S = -\left(\frac{\partial I}{\partial T}\right)_v = R \log v - \frac{\delta \Phi}{\delta T}; \quad c = T\left(\frac{\partial S}{\partial T}\right)_v = -T\frac{\partial^2 \Phi}{\partial T^2} \ldots [5]$$

By double integration of the equation for c, one obtains

$$-\frac{\delta \Phi}{\delta T} = c \log AT; \quad -\Phi = c\, T \log AT - B \ldots\ldots\ldots [6$$

The value for Φ thus obtained transferred into equation [3] completely determines the free energy of a body subject to the equation of state [1]. From this follow important consequences.

Equation [3] in its turn gives by derivation the following equations for entropy S and heat capacity at constant volume C_v:

$$S = -\left(\frac{\partial I}{\partial T}\right)_v = R \log (v - \alpha) + \frac{\frac{\partial \phi}{\partial T}}{v + \beta} + c \log AT$$

$$C_v = T\left(\frac{\partial S}{\partial T}\right)_v = \frac{T\frac{\partial^2 \phi}{\partial T^2}}{v + \beta} + c \ldots\ldots\ldots\ldots [7]$$

This expression for C_v would *a priori* indicate that the Van der Waals equation cannot agree with facts as observed. If ϕ reduces not only a constant but, what is more, to a linear function of temperature, then $\frac{\partial^2 \phi}{\partial T^2}$ becomes zero, and C_v becomes constant, a conclusion clearly inacceptable except, perhaps, for monatomic bodies.

The application of equation [7] to the state of saturated fluids is of particular interest. If S_1, v_1 and S_2, v_2 represent the entropy and volume of a body in the state of a vapor and in the state of a liquid respectively, under tensions P and T, then the heat of vaporization of the liquid is equal to $T\ (S_1 - S_2)$, whence the following equation is derived, which indicates the heat of vaporization L:

$$\frac{L}{T} = S_1 - S_2 = R \log \frac{v_1 - \alpha}{v_2 - \alpha} + \frac{\partial \phi}{\partial T}\left(\frac{1}{v_1 + \beta} - \frac{1}{v_2 + \beta}\right) \ldots\ldots [8]$$

v_1, v_2 and P are determined as functions of temperature by the three known relations

$$\frac{P}{(v_1 - \alpha)(v_2 - \alpha) - (\alpha + \beta)^2} = \frac{\phi T}{(v_1 + \beta)^2 (v_2 + \beta)^2}$$

$$= \frac{RT}{(v_1 - \alpha)(v_2 - \alpha)(v_1 + v_2 + 2\beta')} \ldots [9]$$

$$\frac{1}{v_1 - v_2} \log \frac{v_1 - \alpha}{v_2 - \alpha} = \frac{(v_1 - \alpha)(v_2 - \alpha)(-\alpha + \beta)^3 + (v_1 + \beta)(v_2 + \beta)}{(v_1 - \alpha)(v_2 - \alpha)(v_1 + v_2 + 2\beta)} [10]$$

which unfortunately cannot be solved with respect to the unknowns v_1, v_2 and P. But Clausius has published a table which meets this difficulty in so far as equations of state of the type shown in [1] are concerned, by permitting them to be evaluated directly.

The author shows that equation [8] can be written as

$$\frac{L}{T} = R\lambda + \frac{1}{y}\frac{\partial \phi}{\partial T}\left(\frac{1}{y_1 + 1} - \frac{1}{y_2 + 1}\right) \ldots\ldots\ldots\ldots [11]$$

and hence the heat of vaporization can be easily calculated for any given temperature by the Clausius table. The value of this temperature transferred into the first of the following three equations

$$x = \frac{27}{8}\frac{\gamma RT,}{\alpha(T)} \quad y = \frac{v - \alpha}{\gamma}, \quad z = \frac{8\gamma P}{RT} \ldots\ldots\ldots\ldots [12]$$

giving x, and once the value of x is known the Clausius table will give all the other magnitudes.

If the function ϕ be replaced by a constant as in the Van der Waals equation, [11] takes the very simple form

$$L = \lambda\, R\, T \ldots\ldots\ldots\ldots\ldots\ldots\ldots [13]$$

the value of λ being, according to the first of the equations [12], the one which corresponds to the reduced temperature $x = T/T_c$, so that it is only necessary to know the critical temperature T_c of a body in order to determine the heat of vaporization at any temperature.

The writer discusses the application of this equation to monatomic bodies but, because of lack of experimental data, comes to no definite conclusions (Sur la détermination de l'énergie libre par l'équation d'état de Clausius, E. Ariès, *Comptes Rendus des Séances de l'Académie des Sciences*, vol. 163, no. 24, December 11, 1916, pp. 737-741, *t*).

The report of the meeting of the Society of Automotive Engineers in the February issue of the Journal (p. 183) was written by John Younger, Mem.Am.Soc.M.E. By a regrettable error, his signature was omitted.

Motor Boat Show

The Thirteenth Annual Motor Boat Show was held under the auspices of the National Association of Engine and Boat Manufacturers in New York City, at the Grand Central Palace, from January 27 to February 3, 1917.

It did not show anything revolutionary in the way of either boats or engines, but was a good proof of the steady progress made in this line of engineering in the United States. As compared with the last year's show at the Grand Central Palace and the previous shows at Madison Square Garden, one was impressed by the apparent change from a trade which aimed mainly to serve the amateur and sportsman, to one which is apparently coming to relate to straight commercial work. The number of small engines exhibited was less than at any previous show, but there were many large engines, apparently intended for either large pleasure boats or heavy- and medium-duty commercial boats.

The general design of the engines also showed undoubted signs of improvement. In the majority of cases the workmanship is better, the wiring properly enclosed, magnetos take the place of dry-cell batteries and spark coils, more attention is paid to the balancing of the engine, and a decided improvement in the design of the lubricating system is noticeable.

Considerable attention was attracted at the show by the U. S. Navy patrol-type boats. These boats are about 45 ft. long and 10 ft. deep and have been indicated as a sample of what the U. S. Government would like yachtsmen to build as a combination yacht and patrol boat. One type exhibited at the show is powered with a pair of 150-hp. (each), six-cylinder, 6-in. x 6-in. Van Blerck motors, capable of driving the boat fully loaded at a speed of 25 mi. per hr. Her fuel capacity is about 500 gal., which gives her a cruising radius of 300 miles.

Two Duesenberg motors were shown, one for motorboat use and the other an aeronautical type. For the latter an output of 1 hp. per 3 lb. of overall weight is claimed.

An interesting type is the silent-valve Driggs marine engine, exhibited by the Driggs Ordnance Co., of New York City. Fig. 12 shows the valve employed in the 4-in. x 6-in. six-cylinder engine. The inlet and exhaust ports have many times the area of valve openings of poppet-valve motors of equal bore and stroke. The gas passages are comparatively unrestricted, as there are no sharp turns or sharp corners to retard the flow of gas. This helps to obtain not only a full charge on the intake stroke but also complete scavenging on the exhaust stroke. The valve shaft is driven by means of a gear from the time shaft. A steep-pitch adjusting screw engages in a thread in the valve. The valve driving spring forms the driving connection between the valve drive shaft and the valve. As the valve heats it expands and requires greater effort to drive it. This extra effort causes the valve shaft to advance angularly a fraction of a degree relatively to the valve against the action of the spring. In so doing the screw tends to screw out of the thread of the valve and move the valve upward in its tapered seat. The valve lifts only enough to make the driving effort normal. This effort is normal when clearance is such that there is a film of oil of almost infinitesimal thickness between the valve and its seat. The adjusting mechanism controls this gradually so that the oil film is maintained at a constant thickness.

A shallow-draft boat of the vacuum tunnel type has been exhibited in model. In this boat the propeller does not project beneath the bottom of the boat, and the blades are therefore fully protected at all times. Above the propeller chamber and connecting with it is placed a standpipe or vacuum chamber. From the top of this standpipe the air is exhausted by a small vacuum pump, which needs only to be operated for a moment in order to fill the tunnel and vacuum chamber. Atmospheric pressure forces the water up, filling the tunnel or wheel chamber and the standpipe or vacuum chamber above it. This column of water can be raised and maintained at any desired height from a few inches up to about 28 ft., the limit of atmospheric pressure. For every foot that the water is raised over the wheel the propeller is given solid, hard water of substantially the same characteristics that it would have if the propeller were operating the same number of feet below the water level. No data were given out as to any tests of the efficiency of this type of boat.

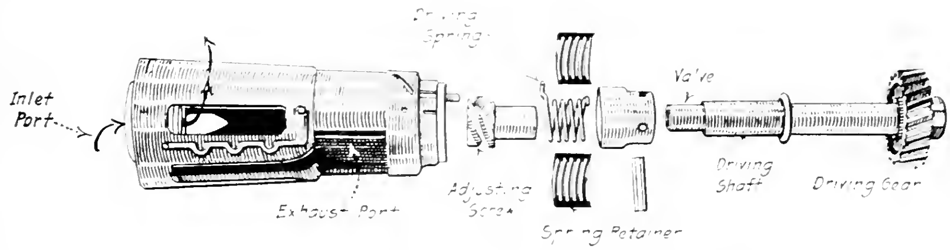

Fig. 12 Russell Silent Valve for Marine Engines

First Pan-American Aeronautic Exposition

The First Pan-American Aeronautic Exposition was held in New York City, February 8-15, and represented broadly the great progress made in American aeronautical engineering since the day when Wilbur Wright flew the first heavier-than-air machine in the world at Kitty Hawk. The original Wright machine was included among the exhibits, and was fittingly located right opposite the entrance to the exhibition. So great has been the progress in the thirteen years which have elapsed since the historic day of its flight, however, that in many respects the machine would be taken for a freak nowadays. It is remarkable, however, that in the essentials of construction comparatively little progress has been made: the location of the engine, the arrangement of the planes, the system of control, the methods of balancing, are fundamentally the same in the machines of today as in the old Wright biplane. But a tremendous progress has been achieved in those engineering details which convert a rough experiment into a practical success, to which fact the exhibits of present types of machines testified.

While the number of machines and engines exhibited was comparatively small, the quality of the products of American manufacturers was apparently as high as that of manufacturers in Europe, in so far as we are allowed to know of the progress there. It is true, however, that both the planes and the motors shown were smaller than what we understand to be the best European products of the same kind.

Very little was exhibited which was not known from previous published descriptions. A construction which attracted considerable attention was the aero-limousine at the stand of the Curtiss Aeroplane Corporation. This is a car

designed to run on the ground but also able to rise in the air. It is provided with small diameter disk wheels or rubber tires and also aeroplane planes and controls. From an engineering point of view there is considerable doubt as to the practicability of the machine. No spring suspension is provided for the carriage and it is by no means clear how long such a vehicle would be able to run on the ground without having the motor shaken all to pieces. No provision is made for steering the vehicle on the ground; this, however, is not very important, because a considerable amount of steering can be carried out by means of the aero controls. No means for braking the vehicle on the ground are provided. From statements made in the press, however, it appears that this aero-limousine has been built for use in inspecting extensive sheep ranges in the West, which would indicate that the conditions of operation of the vehicle may be such as to make it possible to dispense with either high precision in steering on the ground or the necessity for braking.

The Aeromarine Plane & Motor Co. exhibited a new aluminum motor with cast-iron liners, a special distributor, and an electric starter weighing only 20 lb.

An apparent effort has been made to handle the exhaust from the engines in somewhat novel ways. The Witteman-Lewis machine proposes to deliver the exhaust downwards through the bottom plate of the engine. The L. W. F. Co. showed a machine in which the exhaust is delivered rearwards through two pipes about 4 in. in diameter and about 6 ft. long, bending downwards at about half length and then straightening out again and running along the sides of the fuselage. No attempt appears to have been made to provide any kind of a muffler for the machines.

On the whole, while no revolutionary inventions have been exhibited, the exposition shows a healthy state of development of the American aeronautical industry. No machines which could be used for heavy military work or long-range flying were exhibited, which does not, however, mean that American makers cannot build them.

SOCIETY OF AUTOMOTIVE ENGINEERS

In connection with the first Pan-American Aeronautic Exposition, the S.A.E. arranged on February 9 an aeronautic meeting, the first to be devoted entirely to the consideration of aeronautic-engineering subjects.

The morning session was devoted essentially to matters of standardization. The program comprised the reading and discussion of two papers, of which only one was actually read.

Jno. J. Rooney, of the Wright-Martin Aircraft Corporation, presented a paper (read by title) on Suggestions For Standard Tests of Aeroplanes. The matter of standard tests becomes of considerable importance in view of the fact that it appears that during the past year manufacturers have had considerable difficulty in obtaining with their machines the performance guaranteed to the Government in their contracts, a condition which in war time might become a national calamity.

In discussing this subject the author stated that it is the policy of some of the manufacturers to force successful performance regardless of the number of alterations in design required for the accomplishment, which the writer considers to be a grave mistake. As the testing field is usually at some distance from the factory and reliable records of engineering value are seldom kept on the field, the engineers often are deceived regarding the performance of the machine, especially as they are ignorant of changes that have been made in the machine to make it come up to expectations—changes often important enough to alter radically the original design.

The author suggests, therefore, the standardization of field tests. He proposes to use standard test forms for the aeroplane itself, the engine, propeller and for recording aeroplane data; and emphasizes the necessity of keeping track of the conditions under which machines are tested, with due regard to conditions under which they are to be flown.

The author comes to the conclusion that performance productions can be made more reliable by satisfactorily checking laboratory experiments with actual field tests, and advocates means for increasing the value of field tests.

The paper personally read by F. G. Diffin, of the Erie Specialty Co., Erie, Pa., on Standardization of Metal Parts for Aeronautic Use, told of some of the troubles of the manufacturer of metal fittings for aeroplanes and of some ways of minimizing if not entirely eliminating them.

The troubles of the part manufacturers are in the first place due to the multiplicity of the parts. Of screw-machine products alone on a well-known type of machine there are over three thousand separate parts. Many of these call for from two or three to as many as ten operations looking to their completion. Factories have today orders for one specific size of bolt for practically the same use on various makes of machines calling for the use of six different metals. They are asked also to make these bolts in over sixty different lengths, and practically the same condition exists in eight different diameters. It will thus be seen that should such specifications become general it would be necessary on hexagon-head bolts alone to manufacture 2880 separate items in order to fill aeroplane requirements. An additional bolt complication is the varying thickness of head called for by the different manufacturers. The same situation exists in rod and yoke-end points as well as in castle nuts.

This divergence in size and material called for creates troubles and delays not only for the manufacturer of parts but also for the aeroplane and engine manufacturer and user, and could the metal fittings become standardized the aeroplane manufacturer would find that the cost of many of these parts would be but a small fraction of the present cost.

In conclusion, the writer made specific recommendations for standardization, covering bolt dimensions and materials, rod and yoke-end points, and nut requirements.

In the discussion which followed an important difference between fittings for aircraft and automobiles was brought out, viz., that while in automobiles the matter of weight is practically entirely neglected and the matter of cost is preëminent (secondary of course only to that of safety), in the aeroplane, at least at present, the matter of weight is of greater importance than that of cost. Further, the shape of the fittings, which is scarcely considered at all in automobile construction, becomes of importance on aeroplanes as it affects unfavorably or otherwise the harmful air resistance of the machine. On the whole, however, all the discussors expressed themselves in favor of the adoption of some means towards the standardization of parts.

Henry Souther, Mem.Am.Soc.M.E., Chairman of the afternoon meeting, introduced the subject by a brief talk on the progress of aviation in this country and called attention to the urgent necessity of greater publicity for this new branch of locomotion. He called attention to the often neglected fact that actually a very large number of flights are made every day, flights of which not a mention appears in the papers.

On the other hand, the comparatively few mishaps and accidents are given wide publicity, with the result that in the minds of the public an entirely erroneous impression is created, both as to the state of the art and as to the work actually carried on.

American Society of Heating and Ventilating Engineers

The Thirty-Third Annual Meeting of the American Society of Heating and Ventilating Engineers was held at the Engineering Societies Building, New York City, on January 16-18, 1917. J. Irvine Lyle was elected president.

An amendment to the constitution was offered by chapters to provide for chapters to be represented in the council, the representative to have no vote.

Of the reports presented the most interesting one was that of the committee appointed by the New York Chapter to consider a standard test for heating boilers. The purpose of this test is stated to be the determination of the capacity and efficiency of heating boilers under conditions approaching as nearly as possible those under which the boiler is to be installed. The specific object is the determination of the amount of steam which a boiler will furnish when burning a definite capacity of coal per hour in the manner for which it was designed. Therefore the schedule covering the report of tests will provide only for those items which are essential to determine the proper capacity of the boiler for commercial or sales purposes. No suggestions are made on this question of commercial rating or capacity except that as a basis of comparison the item "fuel available" should be calculated from area of firebox and depth to center of firedoor not exceeding 20 in. less 20 per cent for reserve; and item "time fuel available will last" figured on the basis of 8 hours.

The present report endorses the formula for calculating the rate given by the 1913 Committee in their report, in the following modified form:

Let C represent the pounds of fuel available for one firing period; let T represent the time fuel available will last; let E equal the total B.t.u. considered available per pound of fuel at boiler outlet, not exceeding results shown by tests.

Then CE/T represents the boiler capacity per hour in B.t.u. If rating is desired in equivalent square feet of direct radiation, divide the capacity in B.t.u. by 250 for steam and 150 for hot water.

American Institute of Electrical Engineers

The fifth annual mid-winter convention was held February 14-16 in the Engineering Societies Building, New York City.

The majority of the papers were on strictly electrical subjects, but in addition to these Major John H. Finney and Captain J. H. Cuntz read addresses on the part which engineers in general and electrical engineers in particular may take in military preparedness in its broad sense.

Professor R. A. Millikan of the University of Chicago read a paper on Modern Physics in which he spoke of the relations between physical research and electrical engineering.

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general; *h* historical; *m* mathematical; *p* *practical;* *s* statistical; *t* theoretical. Articles of especial merit are rated *A by the reviewer.* Opinions expressed are those of the reviewer, not of the Society. The Editor will be pleased to receive inquiries for further information in connection with articles reported in the Survey.

The Interisland Steam Navigation Company of Honolulu, is preparing to replace the old steam engine and boilers of its large passenger and freight steamer *Mikahala* with a single 320-hp. Type M Bolinder engine, which is equivalent in power to a steam engine of 440 indicated horsepower. (*Motorship*, December 1916)

A substitute for platinum, according to *The Ironmonger* (Jan. 27, 1917), is an alloy having the following percentage composition: copper, 6.42; manganese, 0.98; silicon, 1.04; tungsten, 2.13; nickel, 60.65; aluminum, 1.09; iron, 0.76; chromium, 21.07; molybdenum, 4.6. This alloy is said to have a high melting point and to be highly resistant to acids, making it capable of replacing platinum in many cases.

Castings of nichrome intended to withstand temperatures of from 1000 deg. fahr. up, without corroding, are covered by U. S. patent No. 1,190,652. The alloy contains 60 per cent of nickel, 26 per cent of iron, 12 per cent of chromium, and 15 per cent of manganese, the latter being incidental and not essential. If the carbon content is under 0.40 per cent, the alloy can be machined, rolled or forged. It is said to be suitable for valves and valve seats of internal-combustion engines.

John D. Northrop, of the United States Geological Survey, Department of the Interior, estimates that during the year just closed 292,300,000 barrels of crude petroleum was produced and marketed in the oil fields of this country. This quantity is greater by 11,000,000 barrels, or 4 per cent, than the output in 1915. In addition to the quantity of oil produced and marketed in 1916, several million barrels were produced and placed in temporary field storage in Kansas and Oklahoma.

Three 3000-kw. power plants are now operated by volcanic steam at Larderello, in Central Italy, according to *The Electrical World* (Dec. 23, 1916), and supply three-phase energy for transmission to Florence, Leghorn and many smaller cities. The natural steam, which is obtained from 12-in. to 20-in. pipes sunk from 300 to 500 ft. below the surface of the ground, is of a corrosive nature and is not used directly in the turbo-generators; instead, it is applied like fuel in specially constructed multitubular boilers, generating therein steam that after use in the turbo-generators is condensed and pumped back into the boilers.

In anticipation of the day when, on account of the advancing cost of gasoline and other products obtained from petroleum, it might be found commercially profitable to utilize some of the enormous supply of petroleum to be derived from the distillation of the vast deposits of so-called hydrocarbon shales of the Green River formation of northwestern Colorado and northeastern Utah, the U. S. Geological Survey has for three years been making field investigations of them.

Very rough but cautious calculations of the contents of the shale in parts of the area examined indicate that the distillation of shale from beds over 3 ft. thick in Colorado alone will yield more than 20,000,000,000 barrels of crude oil, from which more than 2,000,000,000 barrels of gasoline can be extracted by ordinary methods.

FUEL AND FIRING

COAL AND ITS ECONOMIC UTILISATION, John S. S. Brame. Journal of the Royal Society of Arts, vol. 65, no. 3346, January 5, 1917, pp. 136-143, 2 figs.

SAVING FUEL IN A LARGE INDUSTRIAL BOILER PLANT, David Moffat Myers. Industrial Management, vol. 52, no. 5, February 1917, pp. 639-650.
The author of this paper is known to our readers as an authority on power-plant practice. He describes the economies that were effected in a large, comparatively modern plant which is noted for the progressiveness of its management. Economies in such a plant, therefore, indicate to some degree what savings might be obtained in the average industrial plant. By no means the least important of the methods used was the establishment of a bonus system for firemen.

UEBER ROHÖLFEUERUNGEN IN HÜTTENWERKEN, Von Direktor L. Schweitzer. Stahl und Eisen, 36 Jahrgang, nr. 49, December 7, 1916, pp. 1174-1180, 13 figs.
Crude oil firing in metallurgical plants.

LIBRARY NOTES

From the Library of the United Engineering Society, Engineering Societies Building, New York. Includes Accessions to the Libraries of the Four Founder Societies

According to an agreement made by the thoughtful kindness of Mr. Theodore N. Vail, such volumes of the large Dering collection of early books on electricity which he presented to the Massachusetts Institute of Technology several years ago as were found to be duplicated in their library have now been offered to the American Institute of Electrical Engineers as a gift. Such as are not already in the Institute's collections will be added to the Library.

The Library has acquired by purchase at auction an extensive collection of early works on technical subjects, especially the metallurgy of iron and steel, from the library of the late John B. Pearse. Mr. Pearse was associated with Alexander Holley and others in early steel manufacture, making the first Bessemer steel for rails in this country. Among the purchases was an edition in Latin of Pliny's "Historia Naturale," printed in Venice in 1489; John Webster's "Metallographia," London, 1671; Schonberg's "Ausfuehrliche Berginformation," Leipzig, 1693; Pomet's "Histoire Naturale des Drogues," Paris, 1694; Paracelsus' "Buecher und Schriften," Basle, 1589-91; John Muller's "Treatise of Artillery," Philadelphia, 1779; Libavius' "De Metallorum," Frankfort, 1599; Jacob Leupold's "Schauplatz des Grundes Mechanischer Wissenschaften" in nine volumes with copper plates, Leipzig, 1724-39; Beyer's "Theatrum Machinarum Molarum," Leipzig, 1735; and a large collection of works on varnish.

Reference lists on the following subjects have recently been compiled in the Library:

Bauxite and Aluminum Sulphate
Metric System
Mining in China
Wooden vs. Steel Water Pipe
Standardizing Rates of Pay
Disposal of Tailings by Electric Power
Electrolytic Zinc
Aluminum
Barium Chlorate
Street Traffic Regulation
Central Station Accounting
Household Refrigeration
Tumbling

Copies of these lists are available. The library is now compiling an extensive bibliography on nickel.

The process of moving the collections of the American Society of Civil Engineers to the United Engineering Society shelves has begun; several weeks must elapse before it is completed.

Few members of the Founder Societies seem to realize the facilities offered by the Library Service Bureau for making translations. Any article in any European language can be translated for members. German, French, Spanish, Italian, Swedish, Danish, Dutch, Russian, Bohemian, Servian and Japanese, can be covered by regular translators employed by the Service Bureau. The rates are lower than those charged elsewhere for technical translation.

How to Measure Screw Threads. Bulletin No. 1.

This bulletin is issued as a step toward the promotion of standardized methods for both the casual measurement and continuous inspection of screw-cutting tools and their products. In theory, screw-cutting tools are supposed to reproduce their own threads. They do not always accomplish this in practice, largely because of the condition surrounding the application of power to them. Attention is therefore called to this fundamental idea, namely: it is not the tools that have to interchange, but the work done by them. W. P. C.

PERSONALS

In these columns are inserted items concerning members of the Society and their professional activities. Members are always interested in the doings of their fellow-members, and the Society welcomes notes from members and concerning members for insertion in this section. All communications of personal notes should be addressed to the Secretary and items should be received by March 15 in order to appear in the April issue.

CHANGES OF POSITION

John O. Heinze, until recently identified with the John O. Heinz Company, Springfield, O., has become associated with The Simms Magneto Company, East Orange, N. J.

Wilbur C. Prior, formerly chief draftsman of The Morrow Machine Company, Hartford, Conn., has accepted a similar position with Eaton Crane and Pike Company of Pittsfield, Mass.

Royce L. Beers, until recently assistant fuel engineer with the U. S. Bureau of Mines, Pittsburgh, Pa., has become associated with the U. S. Radiator Corporation, of Detroit, Mich.

Alfred D. White has entered the employ of the Illinois Stoker Company, Alton, Ill. He was until recently district engineer of the Green Engineering Company, with offices in Denver, Colo.

William B. Corbett, designer with the Terry Steam Turbine Company, Hartford, Conn., has become affiliated with the General Electric Company, Lynn, Mass., in the capacity of draftsman.

Armin S. Hoffman, formerly assistant engineer with The Texas Company, New York, N. Y., has become affiliated with the [illegible] engineering department of the Griscom Russell Company, New York, N. Y.

Harold S. Lord has accepted a position with the Ruggles Machine Company, Poultney, Vt. He was until recently connected with the General Electric Company, Lynn, Mass., as mechanical engineer.

Henry E. Eagan, until recently manager of the Atlantic Ice and Coal Corporation, Dublin, Ga., has assumed the duties of chief engineer of the Harris Granite Quarries Company, Salisbury, N. C.

E. Nesdahl, formerly air-conditioning engineer with Warren Webster and Company, Camden, N. J., has become associated with the Braemes Air Conditioning Corporation of Philadelphia, Pa., in a similar capacity.

F. Wm. Hersche, formerly [illegible] foreman of the [illegible] department of the Newton Manufacturing Company, Lewis[illegible], Mass., has accepted a position with the American Locomotive Company, Schenectady, N. Y.

Forrest W. Manker, until recently associated with the B. F. Sturtevant Company, Cleveland, O., in the capacity of district manager, has become identified with the American Incandescent Heat Company, Boston, Mass.

Frank J. McCarty has become identified with the Rudel-Belnap Machinery Company, Ltd., Montreal, Canada. He was until recently in the employ of Tate, Jones and Company, Inc., Pittsburgh, Pa., as designing engineer.

D. W[illegible] M[illegible], formerly with the Montreal Rolling Mills Branch of the Steel Company of Canada, has become affiliated with the engineering department of the Algoma Steel Corporation, Ltd., Sault Ste. Marie, Canada.

Myron W. Rice, who was until recently in the employ of the American Engineering Company, Philadelphia, Pa., in the capacity of testing engineer, has become identified with the Columbia Chemical Company, of Barberton, O.

Albion R. Davis has joined the staff of the Stone and Webster Engineering Corporation, Boston, Mass., as mechanical engineer. Mr. Davis was formerly connected with Gray and Davis, Inc., in the capacity of chief draftsman.

John Airey, assistant professor of engineering mechanics at the University of Michigan, Ann Arbor, Mich., has accepted the position

[illegible] for munitions for the British Government with headquarters at Chicago, Ill.

Kenneth White, for the past seven years chief engineer of the By-Products Coke Corporation, Chicago, Ill., has assumed the duties of conveying-belt engineer of the Manhattan Rubber Manufacturing Company, Passaic, N. J.

Thomas F. [illegible], until recently in the employ of the American Synthetic Dyes, Inc., Newark, N. J., as assistant master mechanic, has become affiliated with the d[illegible]ning department of The Chile Exploration Company, New York.

L. C. W[illegible], for five years division superintendent of the Cygnet Division of The Buckeye Pipe Line Company at Cleveland and Lima, O., has resigned to accept a position with the Mid West Refining Company at Casper, Wyoming.

Claude M. Garland, formerly mechanical engineer with Woodmansee and Davidson, Chicago, Ill., has been placed in charge of the newly organized power department of the Allen and Garcia Company, with headquarters in Chicago, Ill.

A. L. Roberts has resigned his position as designing engineer with The Crown Cork and Seal Company, Baltimore, Md., and has accepted a similar position in the construction department of the Bethlehem Steel Company, South Bethlehem, Pa.

Ralph C. Chestnutt has become associated with the engineering department of the Willys-Overland Company, Toledo, O. He was formerly connected with the Maxwell Motor Compaany, Inc., Detroit, Mich., in the capacity of layout draftsman.

Joseph E. Sheedy has assumed the duties of assistant to the president of the Seattle Construction and Dry Dock Company, Seattle, Wash. He was formerly general superintendent of the Inter Island Steam Navigation Company, Ltd., Honolulu, Hawaii.

Harry H. Bates, recently connected with the Norfolk and Western Railway Company, Bramwell, West Va., as power director, has accepted the position of assistant boiler superintendent of the Hopewell, Va., works of the E. I. duPont de Nemours and Company.

R. K. Stockwell, who has been chief engineer and superintendent for the Braden Copper Company, of Rancagua, Chile, for the past five years, has opened an office in Salt Lake City, as engineering and sales representative of the Robins Conveying Belt Company.

Eric H. Peterson, formerly mechanical and refrigerating engineer with the Ford Motor Company, Detroit, Mich., has assumed the duties of chief engineer with the Vogt Brothers Manufacturing Company, formerly the National Foundry and Machine Company, of Louisville, Ky.

Dr. W. F. M. Goss, Past-President, Am.Soc.M.E., dean of the College of Engineering of the University of Illinois, has resigned to accept the presidency of the Railway Car Manufacturers' Association, of New York. The resignation will take effect as soon as Dr. Goss can be relieved.

W. H. Marshall, formerly president of the American Locomotive Company, is to become associated with J. P. Morgan and Company. It is understood that recognition of the successful execution of munition contracts by the American Locomotive Company during Mr. Marshall's administration has led to his new connection.

Paul H. Lange, for the last 6½ years chief engineer of the Niagara Machine and Tool Works, Buffalo, N. Y., formerly chief engineer of The Toledo Machine and Tool Company, Toledo, O., is now connected with the Max Ams Machine Company, Bridgeport, Conn., as engineer and manager of their press manufacturing department.

ANNOUNCEMENTS

Walter B. Gump has joined the staff of Armour and Company, Chicago, Ill., as mechanical engineer.

Max Friedlander has become associated with the American Radiator Company, Institute for Thermal Research, Buffalo, N. Y.

Fred W. Teele was elected vice-president and managing director of the Southern Canada Power Company, Montreal, Canada.

J. A. Malone, until recently connected with the New York office of the Allied Machinery Company of America, is now with the Paris office of the firm.

Sanford E. Thompson announces the formation of a partnership with William O. Lichtner under the name of Thompson and Lichtner, with offices in Boston, Mass.

Stanley D. Winger, sales engineer with The Prest-O-Lite Company, Inc., Chicago, Ill., has been placed in charge of the newly organized railway sales and service department of the company, with headquarters in Indianapolis, Ind.

Wm. A. Cattell, Henry S. Howard and Raymond Ashton announce their association under the firm name of Cattell, Howard and Ashton, Engineers, San Francisco, Cal.

Norman W. Storer, general engineer of the Westinghouse Electric and Manufacturing Company, was elected president of the Veteran Employees' Association of that company.

Elliott H. Whitlock has been recommended by the Chief of Engineers of the War Department for commission in the grade of Major in the Engineer Officers Reserve Corps.

A. L. Humphrey, first vice-president and general manager of the Westinghouse Air Brake Company, Pittsburgh, Pa., has been elected president of the Union Switch and Signal Company, in accordance with merger proceedings of the two companies. Hereafter he will assume the executive work of the two companies.

S. J. Gates, until recently commercial engineer with The Milwaukee Electric Light Company, Milwaukee, Wis., announces the organization of the Gates Engineering Company, commercial engineers. This company is prepared to investigate problems involving the supply of power, the development of new and additional business for municipally or privately owned electric and heating plants, the prospecting of new territory for electric power development, etc.

Charles R. Courteney and Robert E. Cahill, chief draftsman and superintendent, respectively, with the Watertown Engine Company and later with the New York Engine Company, have formed a partnership and will conduct business under the name of the Watertown Engine and Machine Company. The company will make a specialty of repairs and replacements to Watertown engines and boilers, and in addition will do engineering work along the line of testing and adjusting power-plant apparatus.

APPOINTMENTS

Warren D. Lewis has accepted an appointment as chief engineer of the Bradstreet Realty Corporation, New York, N. Y.

William J. Bailey has been appointed eastern sales manager of the United Coal Corporation, with headquarters in the Pennsylvania Building, Philadelphia, Pa.

William Ralph Webster has been appointed assistant chief engineer of the Cambria Steel Company, Johnstown, Pa. He was formerly chief draftsman of the company.

E. P. Roberts, consulting engineer, formerly Smoke Commissioner of Cleveland, O., has been appointed efficiency engineer of the Philadelphia Rubber Works Company, Akron, O.

Elmer F. Backer, formerly in charge of the new designs and experimental work at the Davenport Locomotive Works, Davenport, Ia., has been appointed chief draftsman of the company.

AUTHORS

Charles M. Horton is writing a series of articles on the Drafting Room for the *American Machinist*.

F. H. Newell addressed the February 1 meeting of the Engineers' Club of Trenton on Engineering Coöperation.

Albert A. Cary has contributed an article on Formation of Clinkers in Boiler Furnaces to the February 10 issue of the *Electrical World*.

F. A. Halsey has contributed an article on Metric System in Engineering to the February 1 issue of the *American Machinist*.

Frank Richards is the author of Drill-Sharpening Methods at the United Verde Mine, Arizona, which appears in the February 1 number of *Engineering News*.

Carl G. Barth is the author of Time Studies for Rate Setting as Originated by Dr. F. W. Taylor, which appears in the February 1 issue of the *American Machinist*.

Dwight V. Merrick has contributed an article entitled Object and Method of Taking Time Studies for Rate Setting to the February 8 issue of the *American Machinist*.

Walter Rautenstrauch is the author of Critical Speeds of Rotors Resting on Three Bearings, which is published in the February 1 number of the *American Machinist*.

THE NEW BOOKS

ALL books received by The Journal will be listed under this heading, generally accompanied by brief descriptive notes. Works of special importance to mechanical engineers will be commented on at length by members and others peculiarly qualified by reason of their experience and training. In this issue the list has been enlarged to include the chief publications brought out in the late summer and autumn of 1916.

AUTOMOBILES

Modern Starting, Lighting and Ignition Systems. By Victor W. Page. 5½ x 8 in., 509 pp., 295 illustrations. The Norman W. Henley Publishing Co., New York. $1.50.

BUILDING CONSTRUCTION AND EQUIPMENT

Mechanical Equipment of Buildings. By Louis A. Harding and Arthur C. Willard. Vol. I, Heating and Ventilation of Buildings. 7 x 9¼ in., 621 pp., illustrated. John Wiley & Sons, Inc., New York. $4 (To be reviewed later.)

Practical Safety Methods and Devices. By George A. Cowee. 5½ x 9 in., 434 pp., 128 illustrations. D. Van Nostrand Co., New York. $3. (To be reviewed later.)

Safety Engineering Applied to Scaffolds. 6 x 9 in., 339 pp., 127 illustrations. The Travelers Insurance Co., Hartford, Conn. $3.

ELECTRICAL ENGINEERING

A Laboratory Course of Practical Electricity. By Maurice J. Archbold. 7½ x 9¾ in., 211 pp., 98 illustrations. The Macmillan Co., New York. $1.10.

This book is made up of about one hundred loose-leaf blanks upon which to report the results of the experiments outlined therein, and is designed to be used in connection with any text-book. The experiments are intended to form four semesters of laboratory work, and, beginning with those on simple magnetic laws, range up through battery connections, resistance measurements, etc., to tests and measurements on d.c. and a.c. motors and generators and accessory apparatus. Diagrams showing the arrangement and connections of apparatus in the various experiments are given in an appendix.

Handbook of Machine Shop Electricity. By C. E. Clewell. 4 x 7 in., 461 pp., 315 illustrations. McGraw-Hill Book Co., New York. $3.

HOISTING AND CONVEYING

Elevators. By John J. Jallings. 5½ x 8½ in., 200 pp., 217 illustrations American Technical Society, Chicago, Ill. $1.50.

MACHINE ELEMENTS

Elementary Cams. By Franklin DeR. Furman. 5½ x 9 in., 87 pp., 69 illustrations. John Wiley & Sons, Inc., New York, $1.25.

The author first describes the various types of cams in common use, and then defines the terms employed in the solution of design problems. Following this come explanations of the methods of constructing the several generally used base curves for unit rise of the follower. In the third section, which comprises over half the book, the advantages of designing on a scientific basis instead of by cut-and-try methods are set forth, and illustrative problems are worked out in detail for each of the types dealt with earlier. Short sections on the timing and interference of multi-cam arrangements and on cam mechanisms for reproducing given curves and figures are also included.

Empirical Design. By Leslie D. Hayes. 6 x 9 in., 99 pp., 66 illustrations. Carpenter & Co., Ithaca, N. Y. $1.

Power Transmission by Leather Belting. By Robert T. Kent. 5¼ x 8 in., 120 pp., illustrated. John Wiley & Sons, Inc., New York. $1.25.

Valves and Valve Gears. By Franklin DeR. Furman. Second edition. 6 x 9 in., 253 pp., 237 illustrations. John Wiley & Sons, Inc., New York. $2.50.

MACHINE SHOP PRACTICE METAL WORKING

Automatic Screw Machines. By Douglas T. Hamilton and Franklin D. Jones. 6 x 9 in., 342 pp., 150 illustrations. Industrial Press, New York. $2.50. (Reviewed in this issue.)

English and American Tool Builders. By Joseph W. Roe. 6 x 9 in. 315 pp., 58 illustrations. Yale University Press, New Haven. Conn. $3. (To be reviewed later.)

Forging of Iron and Steel. By Wm. A. Richards. 5 x 8 in., 213 pp. 237 illustrations. D. Van Nostrand Co., New York. $1.50.

Grinding Machinery. By James J. Guest. 5½ x 8½ in., 440 pp. Longmans, Green & Co., New York. $4.

Lathe Design, Construction and Operation. By Oscar E. Perrigo. Revised edition. 6 x 9 in., 460 pp., 341 illustrations. The Norman W. Henley Publishing Co., New York. $2.50.

Oxy-Acetylene Welding. By S. W. Miller. 6 x 9 in., 287 pp., 192 illustrations. Industrial Press, New York. $2.50. (To be reviewed later.)

Plain and Ornamental Forging. By Ernst Schwarzkopf. 5¼ x 8 in. 264 pp., 400 illustrations. John Wiley & Sons, Inc., New York $1.50.

Practical Forging and Art Smithing. By Thomas F. Googerty. 5 x 7¾ in., 144 pp., 89 illustrations. The Bruce Publishing Co., Milwaukee, Wis. $1.

Treatise on Milling and Milling Machines. 6 x 9 in., 400 pp., 267 illustrations. Cincinnati Milling Machine Co., Cincinnati, O. $1.50

MANAGEMENT AND COST ACCOUNTING

Cost Accounting and Burden Application. By Clinton H. Scovell. 5¼ x 7¾ in., 328 pp. D. Appleton & Co., New York. $2. (To be reviewed later.)

Ford Methods and The Ford Shops. By Horace L. Arnold and Fay L. Faurote. 7 x 10 in., 440 pp. The Engineering Magazine Co., New York. $5.

Industrial Leadership. By Henry L. Gantt. 6 x 9 in., 128 pp., 9 charts. Yale University Press, New Haven, Conn. $1.

Manufacturing Costs and Accounts. By A. Hamilton Church. 6 x 9 in., 452 pp., 139 illustrations. McGraw-Hill Book Co., Inc., New York. $5. (To be reviewed later.)

Principles and Practice of Cost Accounting. By Frederick H. Baugh. 6 x 9 in., 194 pp. F. H. Baugh, Baltimore, Md. $2.

The Predetermination of True Costs and Relatively True Selling Prices. By Frederic A. Parkhurst. 6 x 9 in., 104 pp., illustrated. John Wiley & Sons, Inc., New York. $1.25.

Valuation, Depreciation and the Rate-Base. By Carl Ewald Grunsky. 5¾ x 9 in., 387 pp. John Wiley & Sons, Inc., New York $4. (To be reviewed later.)

MARINE ENGINEERING

Land and Marine Diesel Engines. By G. Supino. 6 x 9 in., 309 pp., 99 illustrations. J. B. Lippincott Co., Philadelphia, Pa. $3.75.

The Design of Marine Engines and Auxiliaries. By Edward M. Bragg. 6¼ x 9¼ in., 183 pp., 110 illustrations. D. Van Nostrand Co., New York. $3. (To be reviewed later.)

The Marine Steam Engine. By R. Sennett and H. J. Oram. 6 x 9 in., 502 pp., 414 illustrations. Longmans, Green & Co., New York. $6. (To be reviewed later.)

The Marine Steam Turbine. By J. W. M. Sothern. Fourth edition, 6 x 9 in., 561 pp., 230 illustrations. D. Van Nostrand Co., New York. $6.

MATERIALS OF ENGINEERING

Engineering Chemistry. By Thomas B. Stillman. Fifth edition, 5¾ x 8¾ in., 760 pp., 150 illustrations. Chemical Publishing Co., Easton, Pa. $5. (To be reviewed later.)

Lubricating Engineer's Handbook. By John Rome Battle. 6 x 9 in., 333 pp., 114 illustrations and 16 pp. of ruled log sheets. J. B. Lippincott Co., Philadelphia, Pa. $4. (To be reviewed later.)

Mechanical Technology. By C. F. Charnock. 8½ x 5½ in., 620 pp., 503 illustrations. D. Van Nostrand Co., New York. $3.

Pipe and The Public Welfare. By R. C. McWane. 4¾ x 7¾ in., 165 pp., illustrated. The Stirling Press, New York. $1.

Steel and Its Heat-Treatment. By Denison K. Bullens. 5½ x 9 in., 431 pp., 223 illustrations. John Wiley & Sons, Inc., New York. $3.75.

The Chemistry and Technology of Paints. By Maximilian Toch. 6 x 9 in., 336 pp., 83 photomicrographic plates and other illustrations. D. Van Nostrand Co., New York. $4.

The Metallurgy of Steel. By J. W. Harbord. Fifth edition, 6 x 9 in., 933 pp. (2 vol.), 695 illustrations. J. B. Lippincott Co., Philadelphia, Pa. $12.50.

The Physico-Chemical Properties of Steel. By C. A. Edwards. 6 x 9 in., 229 pp., 181 illustrations. J. B. Lippincott Co., Philadelphia. $3.50.

MATHEMATICS

Elementary Course in Lagrange's Equations. By N. W. Akimoff. 6 x 9 in., 195 pp., 58 illustrations. Philadelphia Book Co., Philadelphia, Pa. $2. (To be reviewed later.)

Engineering Applications of Higher Mathematics. By V. Karapetoff. In 5 volumes, containing problems respectively on (1) Machine Design, (2) Hydraulics, (3) Thermodynamics, (4) Mechanics of Materials, (5) Electrical Engineering. 6 x 9 in., 60 to 115 pp. each. John Wiley & Sons, Inc., New York. $0.75 per vol.

Handbook of Engineering Mathematics. By Walter E. Wynne and William Spraragen. 4 x 6¾ in., 220 pp., 113 illustrations. D. Van Nostrand Co., New York. $2.

Seventy-two pages of this pocket-size work are devoted to the formulæ and methods of algebra, geometry, trigonometry, analytic geometry, calculus, hyperbolic functions and differential equations; 60 pages to the fundamental formulæ of theoretical mechanics, mechanics of materials and hydraulics; 24 pages to electrical formulæ and data, 10 to measurement, 17 to physical and chemical constants, and 29 to mathematical tables. It is intended primarily for students in engineering schools, and the authors have endeavored to make it a handy means of reference to the theoretical and applied mathematics used in engineering.

MECHANICS

Elementary Mechanics for Engineers. By Clifford Newton Mills. 4½ x 7 in., 127 pp., 36 illustrations. D. Van Nostrand Co., New York. $1.

The course given in this book is designed to form the basis for a semester's work of three hours per week, and presupposes a mathematical preparation on the part of the student that includes trigonometry. Principles throughout are briefly stated, it being intended that a thorough comprehension of their meaning and application shall be gained by the solution of problems, of which there are more than three hundred, many of them original.

Hydraulic Flow Reviewed. By A. A. Barnes. 9¾ x 6½ in., 158 pp., 11 plates. Spon & Chamberlain, New York. $4.50.

MUNITIONS

Manufacture of Artillery Ammunition. By L. P. Alford (editor-in-chief), F. H. Colvin, R. Mawson, E. A. Suverkrop and J. H. Van Deventer. 6 x 9 in., 759 pp., 648 illustrations. McGraw-Hill Book Co., New York. $6. (To be reviewed later.)

POWER GENERATION

Coal, Its Economical and Smokeless Combustion. By J. S. Cosgrove. 8 x 5½ in., 273 pp., illustrated. Technical Book Publishing Co., Philadelphia, Pa. $3.

Engineering of Power Plants. By Robert H. Fernald and George A. Orrok. 6 x 9 in., 581 pp., illustrated. McGraw-Hill Book Co., New York. $4. (Reviewed in this issue.)

Gas Engine Ignitions. By E. B. Norris, R. K. Winning and W. C. Weaver. 6 x 9 in., 174 pp., 209 illustrations. McGraw-Hill Book Co., New York. $1.50.

Hydro-Electric Power. By Lamar Lyndon. 6 x 9 in. Vol. I (Hydraulic Development and Equipment), 499 pp., 235 illustrations. $5. Vol. II (Electrical Equipment and Transmission), 360 pp., 154 illustrations. McGraw-Hill Book Co., New York. $3.50.

Riveted Boiler Joints. By S. F. Jeter. 11 x 8 in., 155 pp., 52 illustrations. McGraw-Hill Book Co., Inc., New York. (To be reviewed later.)

Steam Boilers, Their Theory and Design. By H. de B. Parsons. 5¾ x 9 in., 377 pp., 158 illustrations. Longmans, Green & Co., New York. $4. (To be reviewed later.)

Steam Power. By C. F. Hirshfeld and T. C. Ulbricht. 5¼ x 8 in., 428 pp., 232 illustrations. John Wiley & Sons, Inc., New York. $2.

The Callendar Steam Tables. By H. L. Callendar. 5½ x 8½ in., 39 pp. Longmans, Green & Co., New York. $0.80.

PUMPS

Centrifugal Pumps and Suction Dredgers. By E. W. Sargeant. 6 x 9 in., 188 pp., 160 illustrations. J. B. Lippincott Co., Philadelphia, Pa. $3.25.

REFERENCE BOOKS

Elliott's Weights of Steel. Flexible leather, 6 x 9 in., 662 pp. The Penton Publishing Co., Cleveland, O. $20.

Handbook for Machine Designers, Shop Men and Draftsmen. By F. A. Halsey. 8½ x 11 in., 561 pp., 750 illustrations. McGraw-Hill Book Co., New York. $5. (Reviewed in this issue.)

The "Mechanical World" Pocket Diary and Year Book for 1917. 3¾ x 5¾ in., 264 pp. text, and 52 pp. diary. The Norman, Remington Co., American Agents. $0.35.

This handy and inexpensive English compilation of mechanical-engineering information, now in its thirtieth year of publication, has, it is stated, been subjected to a thorough revision. The section dealing with steam and steam engines has been largely rewritten, and a new section on the heat treatment of steel has been added, as well as tables giving dimensions of piston rings and governors, and for the calculation of helical springs.

Mechanical Engineers' Handbook. By Lionel S. Marks. 4½ x 7 in., 1,800 pp., 1,000 illustrations. Flexible leather. McGraw-Hill Book Co., New York. $5. (To be reviewed later.)

Mechanical Engineers' Pocket Book. By William Kent. 4 x 6¾ in., 1,526 pp. John Wiley & Sons, Inc., New York. $5.

REFRIGERATION

Elements of Refrigeration. By Arthur M. Greene, Jr. 6 x 9 in., 478 pp., illustrated. John Wiley & Sons, Inc., New York. $4. (To be reviewed later.)

MISCELLANEOUS

Selling Your Services. 5½ x 8 in., 176 pp. The Sales Service Co., New York. $1.

It is the belief of the authors, whose names are not disclosed, that a man's services are to be marketed to the best advantage by employing the same selling principles that have proved successful in the disposition of other commodities, and with this in mind they have outlined the systematic methods of campaigning which they themselves followed in securing positions of responsibility. The volume includes numerous valuable suggestions regarding the advisability of changing employers and of hiring out to a competitor, hunting out opportunities for employment, the writing of cogent letters of application and situation-wanted advertisements, and procedure at an interview with a prospective employer. Examples of effective letters of application for positions as engineers, salesmen, foremen, correspondents, and accountants are given, which are easily susceptible of modification to suit particular requirements.

Handbook for Machine Designers

Handbok for Machine Designers, Shop Men and Draftsmen. By Frederick A. Halsey, B.M.E., Editor Emeritus of the American Machinist (Author of Slide Valve Gears, The Use of the Slide Rule, Worm and Spiral Gearing, The Metric Fallacy, etc.). McGraw-Hill Book Co., Inc., New York, 1916. Second Edition, revised and enlarged. Cloth, 8½ x 11 in., 561 pp., over 800 illustrations, including many full-page charts. $5.

This book places before the reader a large amount of information which heretofore had been spread over a great number of books, pamphlets, articles, papers, etc., and which for this reason was not available to those for whom this book was mainly written. It makes this information available to the practical man, whereas heretofore it has been available only to the student.

The book is quite broad in its scope and deals with all kinds of machine elements, as well as the strength of materials, mechanics, properties of the chief materials of construction, the study of heat, the steam engine, steam boilers, compressed air, etc., apparently with the aim of bringing together enough information in one volume to enable the designer to study, improve, and, in many cases, to even design a machine. In this the writer has succeeded admirably. Though more than one method or more than one set of formulae are often given, yet the author has succeeded in avoiding all confusion.

The book should be of considerable use to any engineer who has to deal with machinery, and should be of especial use to the draftsman and designer and also to the shop man who wants to be more than a machine operator. The information is given in such a shape that, as a rule, very little mathematical knowledge is required to thoroughly understand the subject, though the author did not make an attempt to leave out all reference to mathematics or the use of mathematical formulae. In many places graphical charts have been given, and many of these charts have been carefully analyzed.

The book is not exactly analytical, yet it offers enough analysis to lift it above a mere compilation and seems to aim to give not merely information but also understanding. Many concrete examples have been given, as well as many comparisons of existing mechanisms.

The material in the book is not original, nor does the author claim originality. An exception should be made as to those items which the author quotes from papers and books written at a previous period by himself, such as worm gears, helical gears, etc.

The book might be compared in its general get-up and its scope to the well known Reuleaux's Konstrukteur, covering somewhat the same ground and with the same thoroughness. Reuleaux's Konstrukteur has been out of date for many years, and no amount of effort would ever bring it again to the same position it once held. Halsey's Handbook will fill for the English-speaking engineers the place which was once occupied by the Reuleaux work.

There are certain chapters which could have been shortened without doing much harm to the book as a whole, among which is the chapter on Cone Pulleys and Back Gears. There are also many tables in the various chapters which, though doubtless of some value, make the book too bulky, and more would have been gained if either some of them had been omitted and thereby the book had been made handier, or else if all or most of the tabulations had been placed in a separate volume. There is considerable duplication in some of the mathematical tables, and it would be of advantage to have these tables thoroughly reviewed before the next reissue of the book.

These minor objections notwithstanding, Halsey's Handbook is an important addition to the engineer's library.

A. L. De Leeuw.

Automatic Screw Machines

Automatic Screw Machines. By Douglas T. Hamilton, Associate Editor of *Machinery* (Author of Automatic Screw Machine Practice, Shrapnel Shell Manufacture, Machine Forging, Bolt, Nut and Rivet Forging, etc.) and Franklin D. Jones, Associate Editor of *Machinery* (Author of Turning and Boring, Planing and Milling, Gaging Tools and Methods, etc.). The Industrial Press, New York, 1916. Cloth, 6 x 9 in., 342 pp., 150 illustrations. $2.[illegible]

The automatic screw machine as a factor in modern mechanical production has become so important and is so widely used that it seems fitting that a treatise specifically directed to it [illegible].

The technical press has of late given much attention to automatic screw machines, their methods of operation, and the class of work which can be economically done on such machines. While every day brings up new problems relating to their use, both the machines themselves and the work done on them have now been sufficiently standardized so that the public can be given some definite information regarding them which can be expected to be of more than transient value.

Such information has been brought together and with new material has been put in form for use by the authors of this book in a way to be of value both to the purchaser and owner of the machines and also to the operator, as well as to the designers of machines and of the tools and auxiliary

equipment required in their use. This work seems well adapted as a help to men who are employed to operate any of the types of machines described, from it they can obtain a better idea of the possibilities of the machine and its method of operation, thus enabling them to secure the best results in their work. It will also inform them as to the working of other makes of machines which at some time they may be called on to operate.

The authors have apparently given a comprehensive treatment of the subject, starting first with a detailed description of the mechanism of a number of well known types of machines, and emphasizing the particular advantages of each and the classes of work for which they are adapted. Thus the particular relative advantages of single- and multiple-spindle machines are discussed, the authors pointing out on what type of work the multiple-spindle machines may give better results by insuring a higher rate of production, and stating reasons why, other things being equal, the single-spindle machine can produce work of a higher degree of accuracy.

Then, following this general description, the authors go into details as to the various tools used in the machines, including instructions as to the correct clearance angles of the tools and as to their hardening; also as to the speeds and feeds required. A chapter also deals with the attachments found useful in extending the scope of the work which can be handled in automatic screw machines, and another gives a detailed description as to methods of laying out cams.

Specific cases are worked out for a variety of kinds of work and for work of different materials in such a detailed way as to be a guide for setting up for other work of similar character, and specific instructions are given as to the procedure of setting up and operating each of the types of machines described.

Finally, a number of special and unusual jobs are described, showing a great range of work which comprises much of a character not usually thought of as being screw-machine work. This, through the ingenuity of specialists, has been made a part of the product of the automatic screw machine, the use of which, for many of these jobs, now outclasses all other methods of production.

LUTHER D. BURLINGAME.

Engineering of Power Plants

Engineering of Power Plants. By Robert H. Fernald, M.E.,A.M.,Ph.D., Whitney Professor of Dynamical Engineering, University of Pennsylvania, and George A. Orrok, M.E., formerly Mechanical Engineer, New York Edison Company. McGraw-Hill Book Co., Inc., New York, 1916. Cloth, 6 x 9 in., 569 pp., 309 illustrations. $4.

"This is not a treatise on power plants. It is simply an epitome of the subject arranged by the authors for convenient classroom use."

These are the first sentences in the preface of this book and may be taken as representing the authors' final opinion of their production, for it is probable that the preface of a book is the last word of the authors.

The statement is clearly a true one. It is not a treatise, because it does not discuss the principles of design either of power-plant units or of power plants themselves. It is an epitome, because it points out just what one finds in power plants of large and small capacity, tells something of how the various units operate, tells much about their comparative economy, and more about the cost of installation and operation.

The authors have certainly accomplished their purpose in writing this book, and it appears at an opportune time.

The development of power engineering during the last decade has been as wonderful as it has been important. New prime movers have been born and have grown to large proportions. The teacher and student, the designing and operating engineer, have realized what a valuable fund of information has been published in the technical press concerning these developments. It has remained for the authors of this book to present the reader with the essentials of the best in power-engineering practice at the present time, not only in this country but abroad.

The authors do not use many words to present their facts; on the contrary, they use short and concise sentences, and the reviewer is impressed with the very large amount of information which the book contains. There are two things which appear peculiar: (a) The order in which the chapters are arranged; (b) the comparatively small space devoted to the electrical generator. The book is very largely descriptive. It contains only simple mathematical formulæ clearly explained and easily understood. It discusses no theories but contents itself with the presentation of facts. It presents the results obtained in the operation of many distinct appliances and many complete plants. It does not place in economic comparison types of equipment which should not be compared.

The book will undoubtedly be used as a textbook as one of the authors has used it—"for *all* senior engineering students"—and all engineering students must know something about the engineering of power plants. With this book as a text the teacher with experience will be able to develop an admirable course of instruction on power engineering in its broadest sense. A goodly number of problems are distributed throughout the book. The problems have a true power-plant flavor and one feels sure the authors have had to solve many of them in practice rather than manufacture them for a textbook.

This book should meet with much favor entirely outside the classroom. The designers, the builders, the operators of power plants will all find much information of value to them in it. The designer will profit by a study of the relative economic-performance curves of various units which he wishes to install, the builder will find the tables of cost extensive, the operator will be able to learn what others have done to reduce operating costs and to observe from the curves what conditions of operation tend toward best performance with a given combination of appliances under varied conditions.

The title Engineering of Power Plants seems to fit the book, for while perhaps two-thirds of its contents relate to burning fuel for making steam and then the use of steam for making power, electricity or heat, the other third takes up internal-combustion engines and gas producers, compressed air, and hydraulic power. A few pages are devoted to the power plant of the steam locomotive.

This is an excellent book: good material well presented; the faults and errors are few.

The names of the authors on the back of the book are a sufficient guarantee of its contents.

It is well when engineers and engineering teachers coöperate. Books will be better as they learn to do so.

It is doubtful if there could be found two engineers whose knowledge of the problems of the engineering of power plants and the teaching of the subject to engineering students, better fitted them for the coöperation which resulted in this work.

U. S. Submarine *K-1*, Just Emerged. The Wireless is Lowered for Submerged Work

THE SUBMARINE

By C. H. BEDELL,[1] GROTON, CONN.

RECENT events have forcibly brought to the attention of the entire world the capabilities of the little boat known as the submarine. All the characteristics of these boats are fascinating; to the engineer on account of the many unique problems that have to be solved; to all of us on account of the many dramatic possibilities in connection with submarine navigation. Since these dramatic possibilities are so great in number, it is surprising that our popular fiction writers have not made more extended use of the submarine. Probably this neglect of such a promising field has been due to lack of the necessary engineering knowledge to handle the subject properly. We have, however, one book on the submarine in the field of fiction that is well written and full of interesting scientific and engineering material. This book is Jules Verne's Twenty Thousand Leagues Under the Sea. I read it as a boy, when it was first published in about 1874, and was fascinated by the picture it gave of life beneath the wave, not imagining that it would ever be my privilege to journey thus in those depths of which we know so little. A short time ago I reread the book, and was again fascinated by it, because it gave me a chance to see how closely we have lived up to that imaginary picture of Jules Verne.

[1] Electrical Engineer, Electric Boat Co.

Presented at a meeting of the New York Section of The American Society of Mechanical Engineers, New York, November 14, 1916.

As far as the handling of a submarine is concerned, whether under way, on the surface or submerged, or at rest on the surface, poised at any depth or resting on the bottom, the boats of the present day are as perfect as the *Nautilus* of Jules Verne. We may even, if we so desire, make our boat so that, when it is at rest submerged, a man with a diving helmet, and entirely disconnected from the submarine or the surface, may pass from it into the sea and explore the ocean floor for an hour or more, as Captain Nemo of the *Nautilus* did. That such construction is not used is due to the fact that there seems to be no material need for such operations. The *Nautilus* was driven by electricity. We also use electricity when running submerged, but we obtain our electricity from storage batteries, while Captain Nemo obtained his in some mysterious way from the sea itself. The great difference between fiction and reality in this case is that the *Nautilus* was able to go around the world with one supply of energy, while we are obliged to come to the surface after one or two hundred miles for the purpose of recharging our storage batteries.

The men on the *Nautilus* are supposed to have been able to see objects at distances up to one-half or three-quarters of a mile by the light of the sun or by powerful electric lamps. While we at this time probably have more powerful electric lamps, it is impossible for us to see any great distance through water, no matter what method of lighting is used. This is true, at least, along our shores as far out as the Gulf Stream.

An enormous amount of sediment is continually being poured into the sea by our rivers and streams, and in addition the endless wash of the waves on our sandy shores constantly tends to maintain the turbidity of the water. I have frequently looked through the periscope of a submarine when resting on the bottom at a depth of 50 ft. The second periscope, some five or six feet away, could easily be seen, but the bow of the boat, 75 ft. away, could not be seen. The suspended matter in the water acts exactly as does fog in the air in preventing distant vision. On account of this fact, all running when totally submerged must be by distance runs, obtained by known speed and time. Of course, in certain waters the limit of vision may be materially increased, as, for example, among the islands of the West Indies or off the coast of Southern California, yet even in such waters it is not probable that one could see more than 100 or 200 ft., and such a distance is not sufficient for purposes of navigation. Thus at one stroke we take away the greatest factor that gives such a charm to Verne's work—the major portion of the control of the submarine must be by vision above the waves.

Another point interesting to consider is that of the pressure per square inch at different depths, for in this connection Jules Verne materially slipped up in his calculations. He tells about Captain Nemo forcing his boat to depths of 6000 or 7000 ft., not realizing that pressures increase nearly half a pound per square inch for each added foot of depth. At 6000 ft. the pressure is nearly 3000 lb. per sq. in., and the *Nautilus,* as described in Verne's work, would not have stood any such pressure. An illustration in the book shows a man seated before a large plate-glass window, and another man swimming in the water outside. This window must have been at least 25 ft. square, and at a depth of 200 ft. it would have to sustain a pressure of about 100 lb. per sq. in., or 175 tons on the window. At 6000 ft. the total pressure would be 5250 tons. Certainly no glass made of the form illustrated could sustain such a load. However, it makes a very pretty picture.

Another point shows Verne's misunderstanding. He states that they had to use all the enormous power of her engines to force the boat down against the great water pressure; the greater the pressure, the greater power it took. This is not according to fact, for if a body is once made heavier than sea water and starts to sink, it will continue until the bottom is reached, if the salt in the sea water remains a constant percentage, a condition which practically exists in the open sea. The question is frequently raised in our newspapers whether a ship sunk by collision or the like will sink to the bottom or go a certain distance and then remain poised. The question was raised at the time the *Titanic* was sunk. The solution of the question rests upon the compressibility of the material of the ship as compared with that of water. If the latter is greater than the former, and the depth is great enough, a point would be reached where the water would be as dense as the material of the ship, and there the ship would remain poised. For the purpose of calculation, let us take the extreme case of a solid steel ball dropped overboard in the open sea. Now, in general, we say that water is incompressible. This statement arose in comparing the compressibility of water with that of a gas, such as steam. When an engineer allows water to get from his boiler into his engine cylinder, and the piston striking this water on the return stroke drives off the cylinder head, he says the water is incompressible. As compared to a gas it is incompressible, but as compared to steel it is compressible; indeed, it is more compressible than steel. Therefore, our steel ball as it descends into the sea and is compressed has water around it that is being compressed at a more rapid rate under the increase of pressure than the steel is. If the depth, and therefore the pressure, is great enough, a point will be reached where the water will be as dense as the steel, and at that point the ball will remain suspended. A calculation based on the compressibility of steel and water shows that the required depth is about 100 miles. As the sea is only some five or six miles deep, it is evident that our steel ball will go to the bottom. Now let us take the case of the ship that has been sunk. When she starts to go down she is heavier than the water around her. The ship, as a whole, is far more compressible than the steel of our ball, and will get relatively heavier as she descends, that is, will sink faster and faster until the bottom is reached. Returning now to the submarine, where we have a hull that is perfectly watertight. Since this hull is composed of circular frames on which is mounted the hull plating, its compressibility is far greater than our steel ball; indeed, it is far greater than water. In consequence, if a submarine is so trimmed down that she is even slightly heavier than water, she will sink to the bottom. This has been conclusively proved in connection with our tests of submarines at 200 ft. Every submarine for the U. S. Government must be taken down to this depth and kept there for ten minutes. In making this test, it is the custom first to anchor the boat where the depth of the water is right, then trim the boat by admitting water into her tanks, trimming her down until she has only a few hundred pounds' buoyancy, then hauling in on the anchor rope. This operation draws the boat down until the desired depth is reached. In one or two cases, in the trimming-down operation, but a small amount of reserved buoyancy was given the boat, and as the boat descended and became compressed this reserved buoyancy was lost and the boat went the rest of the way to the bottom. From the above it will be readily seen that Verne's statement that it took all the power of the engines of the *Nautilus* to drive her into those great depths is not correct. There is one exception to the general statement that a body starting to sink will go to the bottom, and this is where the water is stratified, when large quantities of fresh water from rivers come in contact with the salt sea water. Such a condition exists in the St. Lawrence. Recently in making the 200-ft. depth test in those waters it was found necessary to add 5000 lb. to the water in the tanks after the boat had started to sink in order to get her down to 200 ft. This was due to the fresh water from the river being over the heavier salt sea water.

THE SUBMARINE IN HISTORY

The history of the submarine extends over quite a period of time, as there is a record of such a boat having been built about the year 1624. During the next 150 years the subject was frequently considered by marine engineers, but no construction was undertaken. At the time of our Revolutionary War, the interest in the subject was transferred from Europe to this country, due to the fact that a small submarine had been built by David Bushnell, of Connecticut. This boat was only large enough for one man and shaped like a flattened egg, with its major axis vertical. It was fitted with tanks and pumps, anchor operated from the inside of the boat, screw propeller in the front of the boat, another screw propeller at the top with its axis vertical, rudder and torpedo at the stern, and at the top of the boat a screw operated from within the boat. It is evident that this screw was intended to be worked into the planking of a ship at anchor. The torpedo was fastened to the screw by a line, and when the submarine was moved away the torpedo remained with the screw. The sep-

arating of the torpedo from the submarine started a clock, which in a certain time would explode the torpedo. Bushnell had to educate the public on two points in connection with his boat, the exploding of gunpowder under water and the use of the screw propeller. The propeller had been invented a short time before by another man, but evidently Bushnell's boat was the first on which it was used. During the Revolutionary War a chance at last came to make use of the boat, against a British war ship anchored off Governors Island. Unfortunately, the man who had been conducting the operations of the boat was sick at the time and another had to take his place. Floating down with the tide in the late hours of the night, the submarine was maneuvered until she came under the war ship. The operator in attempting to force the screw into the planking of the ship failed on account of striking metal fittings. Before he could relocate his boat the tide carried him away and he had to give up the attempt. Two other attempts were made against British ships anchored in the Hudson, but these also failed on account of the strong tide. If the anchor of the submarine had been used until the torpedo was attached to the ship, the attempt would have been successful. Public opinion did not support Bushnell in his work, and therefore nothing further was done.

The next submarine of interest is that of Robert Fulton, who launched the *Nautilus* in the Seine in 1801. He conducted many experiments with this boat, but not getting the necessary financial support in France, took the boat over to England. There he created quite a furor, and many experiments were conducted, even going so far as to the blowing up of an old hulk provided for the purpose. The people did not consider the time ripe for that method of warfare, and Fulton again failed to get support. He then came over to this country and succeeded in obtaining a grant of $50,000 from Congress for the conducting of experiments. It is understood that it was Fulton's submarine that was to make an attack on a British prison ship off New London, but the commander of the prison ship hid behind his prisoners and obtained the influence of their friends on shore to prevent the attack. The work with Fulton's submarine was discontinued, as again it seemed that popular opinion was not ready for the use of such ships.

The credit for the first actual service of a submarine in time of war will have to be given to a boat built by Wilhelm Bauer, a Bavarian, who built one such boat for Germany and one for Russia. The boat built for Germany succeeded in breaking up the blockade of the Danish fleet off Kiel. Later, this boat was sunk, due to the collapse of her hull from excessive water pressure, the crew luckily escaping. A few years ago the boat was located during certain dredging operations, was raised, and is now on exhibition in Berlin.

During our Civil War the South became quite interested in the submarine, and several of the boats, called "Davids," were built. These, as were the earlier boats, were all operated by man power, eight men being used to drive the propeller. Many accidents were experienced during the experiments on these boats and several crews were lost. These accidents, however, did not occur when the boats were operating submerged but when on the surface. The small conning tower used was very low, and waves from passing steamers and the like washed over it, causing the boat to sink. New crews were quickly found and experiments continued. At last a chance to use the boat came, and an attack was made on the U. S. frigate *Housatonic*, anchored off Charleston. The attack was made at night, and therefore the boat was operated on the surface only. A spar torpedo was used, as at that time the automobile torpedo had not been developed. It is reported that an officer on the deck of the *Housatonic* saw the submarine approaching the ship, but thought it was a plank floating with the tide. This idea was quickly dispelled, for after a terrific explosion the men who had been on deck found themselves in the water. The *Housatonic* was sunk, and carried down with her the submarine and all her brave crew. It is probable that the smaller boat was sucked into the hole in the larger ship, and held there by the water pressure.

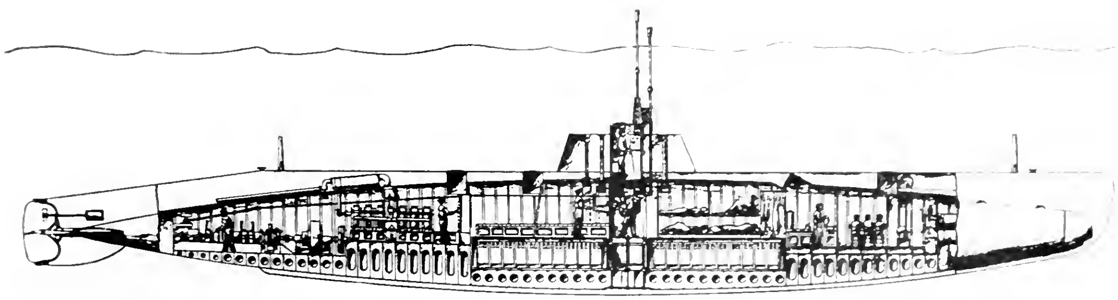

Fig. 1 Cross-Section of a Modern Submarine

Present Day Submarines

During the following twenty-five years many submarines were designed and a few built. None of these, however, proved to be successful. I am going, therefore, to jump to the time of John P. Holland, and describe the submarine of the present day. Holland was an Irishman who came to this country just before the Civil War, a man of but very little education but a bright mind. He was much interested in the fight between the *Monitor* and the *Merrimac*, and soon commenced to consider submarine work. At last he succeeded in getting support for his experiments and built two or three small submarines. His idea being to build a boat that would sink the British Navy, his trend of mind is shown by the name he gave one of his boats, the *Fenian Ram*. His first boats did not amount to much, but he acquired a great deal of experience, discovered what to do and what to avoid, and was then in shape to attempt more extended work. It was at this time that he joined forces with the Electric Boat Company, and the *Holland* was their first product.

Mr. Holland started his work at just the right time, for the internal-combustion gasoline engine giving large power with small space and weight had just been developed and large storage batteries with corresponding electric motors

were to be had. Without this material it is safe to say the submarine would still be in an experimental form.

The general arrangement of the modern submarine follows very closely the design given in sketch form in Fig.

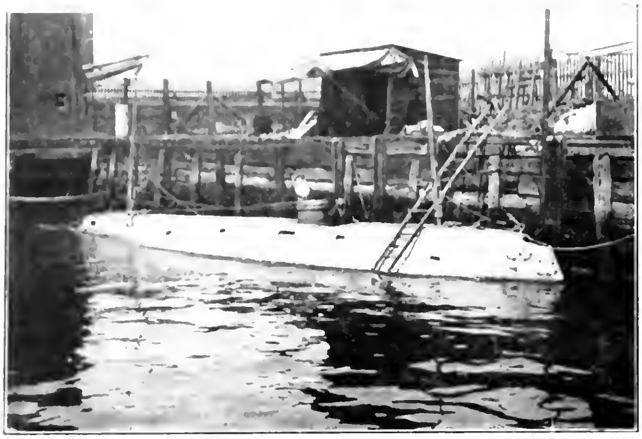

Fig. 2 U. S. Submarine *Holland*

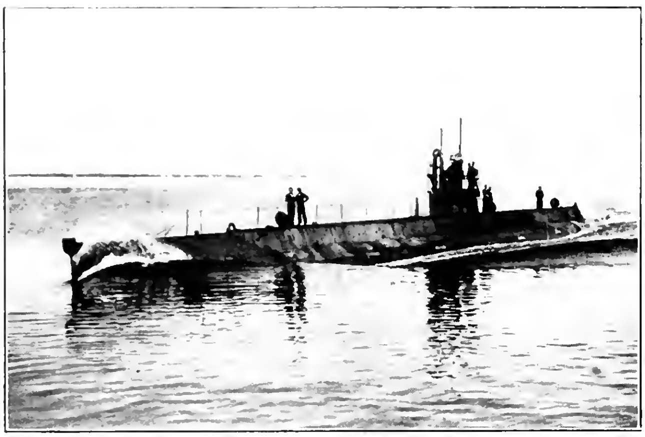

Fig. 3 U. S. Submarine *M-1*

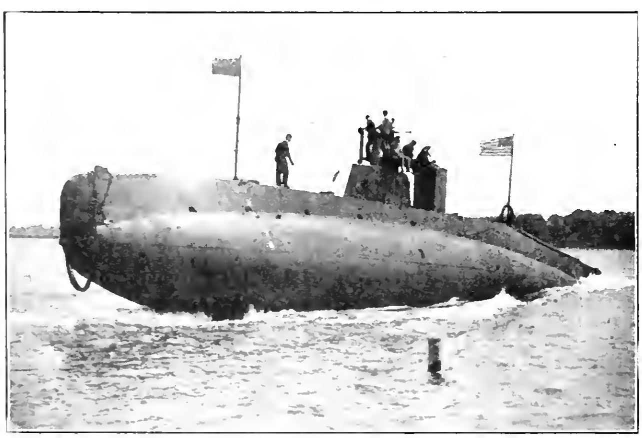

Fig. 4 Launching a Submarine

1. The hull proper is cigar-shaped, since this form is best suited to withstand the pressure of submergence. Above the main hull is a narrow superstructure extending from the bow nearly to the stern. This superstructure may be water-tight, but in general is open to the sea. It serves to house certain external fittings, and forms a deck for the use of the crew. At the bow just within the bow casting is the bow cap, covering the outer ends of four torpedo tubes; two open-

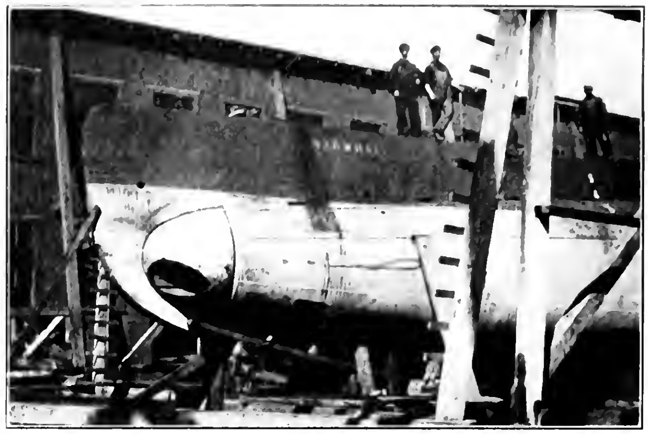

Fig. 5 Bow of Submarine with Bow Cap in Position for Torpedo Firing

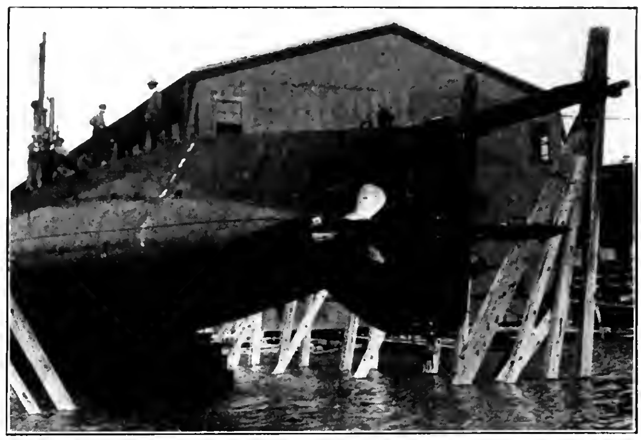

Fig. 6 Stern of a Submarine

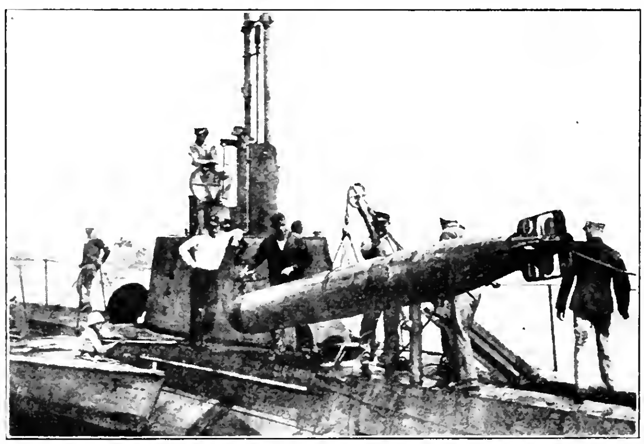

Fig. 7 Taking a Torpedo on Board

ings are made through this bow cap, and by rotating the cap the openings may be placed in line with the different torpedo tubes. These tubes at the inboard end are fitted with doors, so that after the tubes have had the water drained into the

trimming tank which surrounds them, the doors may be opened for the admission of spare torpedoes. Immediately abaft the tubes is space for spare torpedoes, and below the deck, tanks for fuel. In the design shown, the galley is also located in the compartment. In the central part of the boat is the main operating compartment, in which are the levers that control the main ballast, auxiliary ballast, and adjusting tanks, steering and diving wheels, control of all high pressure air lines, periscope and connection to the conning tower. In the two compartments ahead and abaft the central operating compartment are placed the two sections of the storage battery, these batteries being large enough to supply current to the main motors and drive the boat for one hour at $11\frac{1}{2}$ knots, or at low speed to give her a radius of about 100 miles. Around the storage battery are the main ballast tanks. It is in connection with the tanks of a submarine that Mr. Holland showed his genius, and no submarine can be considered a success that does not follow the lines of tank construction that he prescribed. In all the earlier submarines the tanks were constructed large enough to take the maximum amount of water that might be required, and therefore were almost never totally filled. In consequence, as the angle of the boat changed, the water was free to flow from one end of the tank to the other, making it almost impossible to keep the boat properly trimmed. Holland, realizing this condition made it a rule that the main ballast tanks should be of such a capacity that when entirely filled the boat would be brought to the awash condition only, and that the final adjusting of the buoyancy of the boat must be made by the use of a small tank which would have but a small free-water surface if not entirely filled. The main ballast tanks are therefore entirely empty or completely filled. Abaft the storage-battery compartment are the engines, main motors, pumps, air compressors, and at the stern are the after trimming tank, twin screw propellers and the steering and diving rudders. The conning tower is placed over the central operating compartment and in the sketch shown is fitted with one of the periscopes. Steering is done by means of an electric motor controlled by push buttons.

The operation of a boat submerged is quite different from one on the surface. On the surface if a man walks from amidships to the bow, the bow will be depressed, displacing a greater amount of water, and therefore able to sustain the increased weight. When the boat is submerged no change of displacement can occur, and consequently such shifting of weight will cause the boat to take a greater angle. A boat submerged may be likened to a pendulum having a length equal to the distance between the center of buoyancy of the boat and its center of gravity, generally a distance of about sixteen inches, and the weight of the pendulum being the weight of the boat, say 500 tons. A weight moved from amidships to one end of the boat would produce a leverage to swing this pendulum from the vertical, in other words, to cause the boat to take an angle by the bow or stern. As a submarine when submerged will go the way she is pointed, it will readily be seen that change of angle will cause her to change her depth. The man at the diving wheel not only has his wheel and depth gage before him, but also a clinometer, a sort of level by which he can tell the exact angle of the ship and therefore tell whether the boat will change her depth or not as she goes along. As a matter of fact, the boat is swinging up or down most of the time, and it is the duty of the man at the diving wheel to check these motions and control the boat so that she will remain at the depth

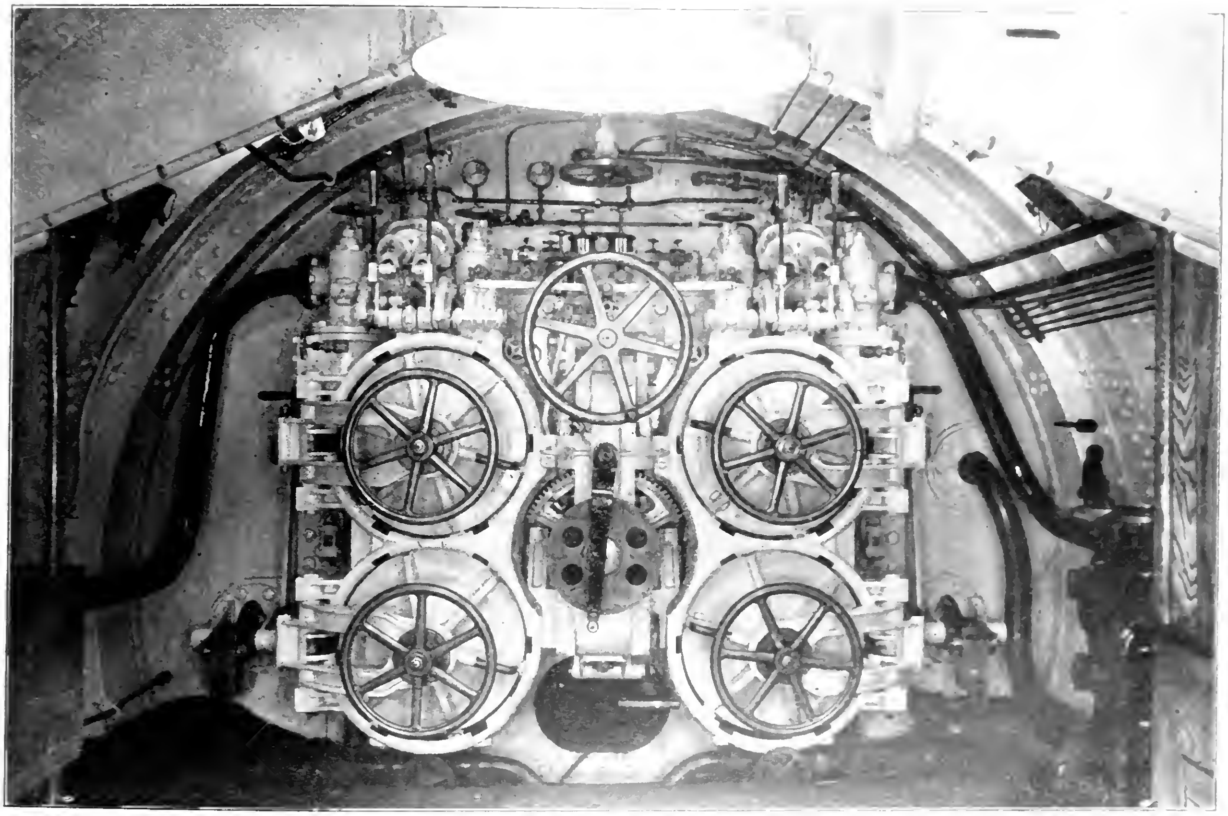

FIG. 8 INNER ENDS OF THE FOUR TORPEDO TUBES

[illegible] body requiring constant attention, and the [illegible] whole [illegible] performance of any duty. In the

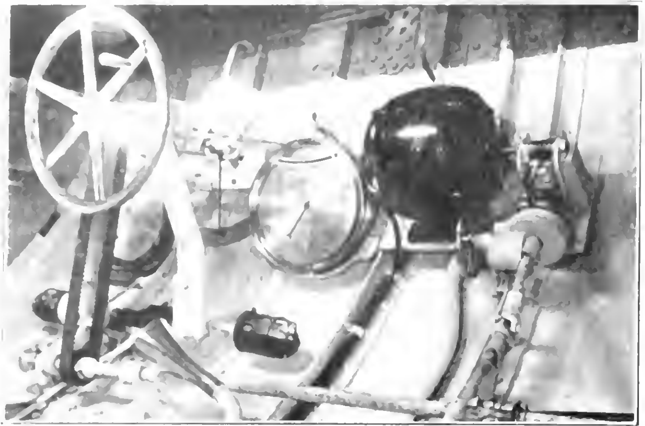

FIG. 9 DIVING CONTROL STATION

small boats first built, great care was exercised that there should be no shifting of weight when the boat was running submerged. In the large boats as now built the weight of a man is such a small percentage of the total weight that quite a change, yet a torpedo from a small boat, if it reaches its mark, is as effective as one from a large boat. It is the fact just mentioned that indicates why a submarine will

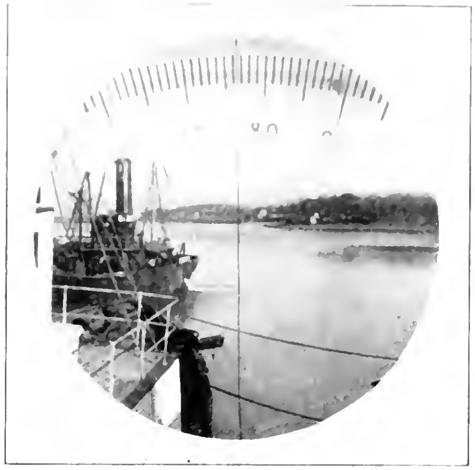

FIG. 10 VIEW TAKEN THROUGH PERISCOPE

retain her usefulness until she is literally worn out. She does not become obsolete as does a battleship as soon as a more

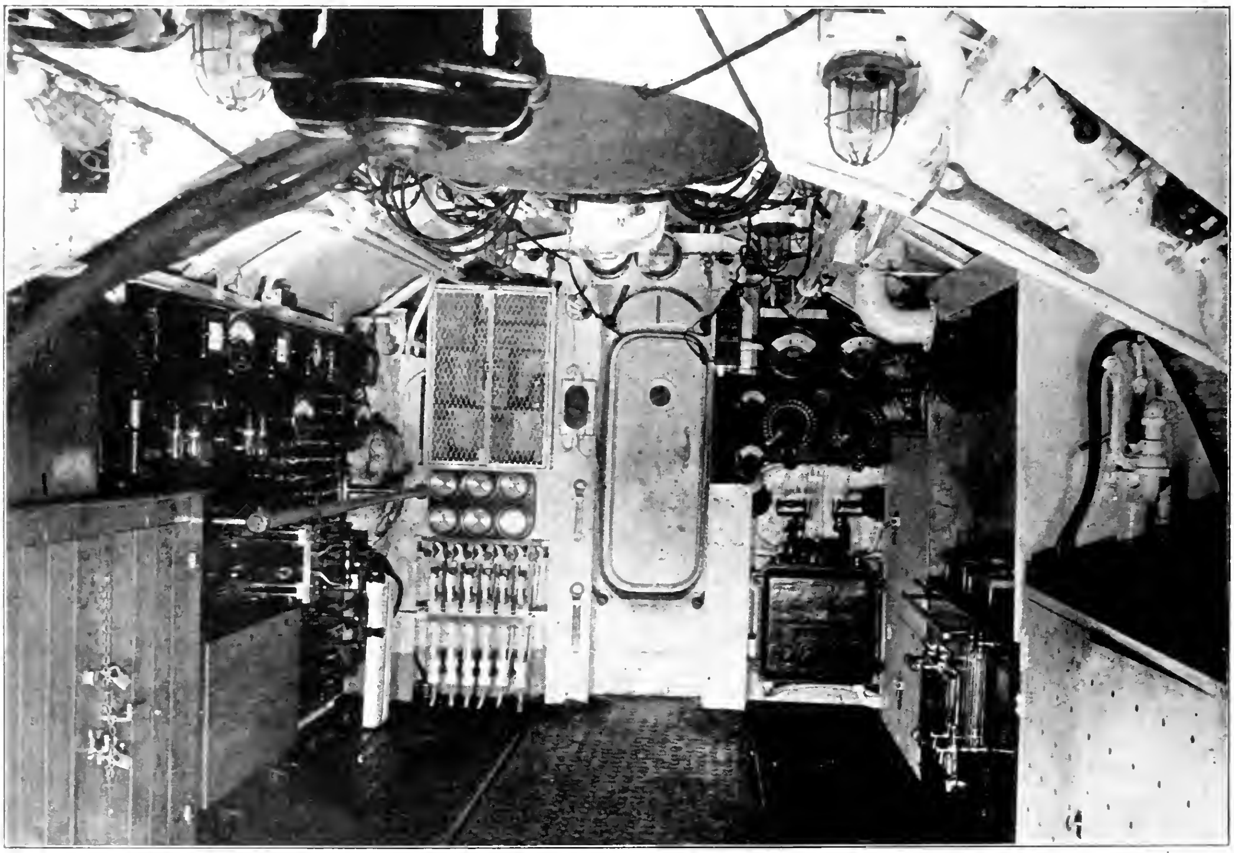

FIG. 11 AFTER END OF CENTRAL OPERATING COMPARTMENT

the momentary movements of the crew may be counteracted by the man at the diving wheel.

EQUIPMENT OF SUBMARINES

From the *Holland* (see Fig. 2) having a length of about 53 ft. to the *M-1* (Fig. 3) with a length about 200 ft. is powerful ship is constructed. The little *Holland* was thus in commission until worn out. Every other submarine built for the U. S. Government is in active service.

At the time the *Holland* was built we had no periscopes. In consequence, the boat had to be handled by "porpoising," that is, running a short distance submerged and then coming to the surface far enough to expose the conning tower, thus

getting a chance for a look around, and then diving. This porpoising can be done very quickly; the boat can pass from the depth of 30 ft. to the surface, line up on the target, have the torpedo fired, and be again below, all in 30 seconds. The advent of the periscope greatly aided submerged navigation, since at all times vision may be had without exposing the hull to the danger of a chance shot. The increased size of the boats has made them far more comfortable, and better sea boats (compare the freeboard of the *Holland* with that of the *M-1*), and better adapted for long service at sea. The development of wireless telegraphy now permits the submarine to keep in touch with the shore, and all submarines are now equipped with this wonderful apparatus, the tall masts required being so constructed that they may be quickly lowered for submerged work.

In the design of a submarine a far greater amount of preliminary work in the line of calculating of weights, disposal of equipment, etc., has to be done than with a surface boat, for not only is there a double motive-power equipment, but the boat must be designed for both surface and submerged work, with all the complicated control apparatus required. Some idea of this construction may be obtained from the illustrations given. Fig. 4 shows the launching of a submarine, the cigar shape of the main hull being of sufficient strength to withstand the pressure of 200 ft. submergence, that is, nearly 100 lb. per sq. in. Fig. 5 represents the bow of a submarine before launching; it shows the bow cap with opening in line with the torpedo tube. When it is desired to close the tubes, the openings of the bow cap are placed under the bow casting. In Fig. 6 we have the stern of a submarine. In addition to the twin screws and steering rudder as used on a surface boat, the submarine has the horizontal diving rudder for steering the boat in the vertical plane. Each submarine can carry at least eight torpedoes. Fig. 7 shows the taking of a torpedo on board, and Fig. 8 shows the inner ends of the four torpedo tubes and escape hatch.

A view of the diving station showing diving wheel and depth gages is given in Fig. 9. On the depth gage below the pointer is shown the curved glass tube of the clinometer. Fig. 10 reproduces a view taken through a periscope. The vertical line is the cross wire and shows the exact direction the periscope is pointed. The scale at the top is a portion of the card of the periscope and shows that the periscope was pointed $76\frac{1}{2}$ degrees from the north towards the east. The after end of the central operating compartment is shown in Fig. 11. This particular boat had an unusually large central operating compartment, at least four times as large as is usually constructed. The dark object at the top of the picture is the lower end of one of the periscopes. Behind this is an escape hatch, the ladder to it having been removed so as not to obstruct the view from the camera. In the left lower corner is the ice box, then comes the battery and auxiliary switchboards. In the center of the picture is the closed door leading into the engine room. To the right of the door is the control equipment of the two main motors and on the right are the electric cooking range and galley sink.

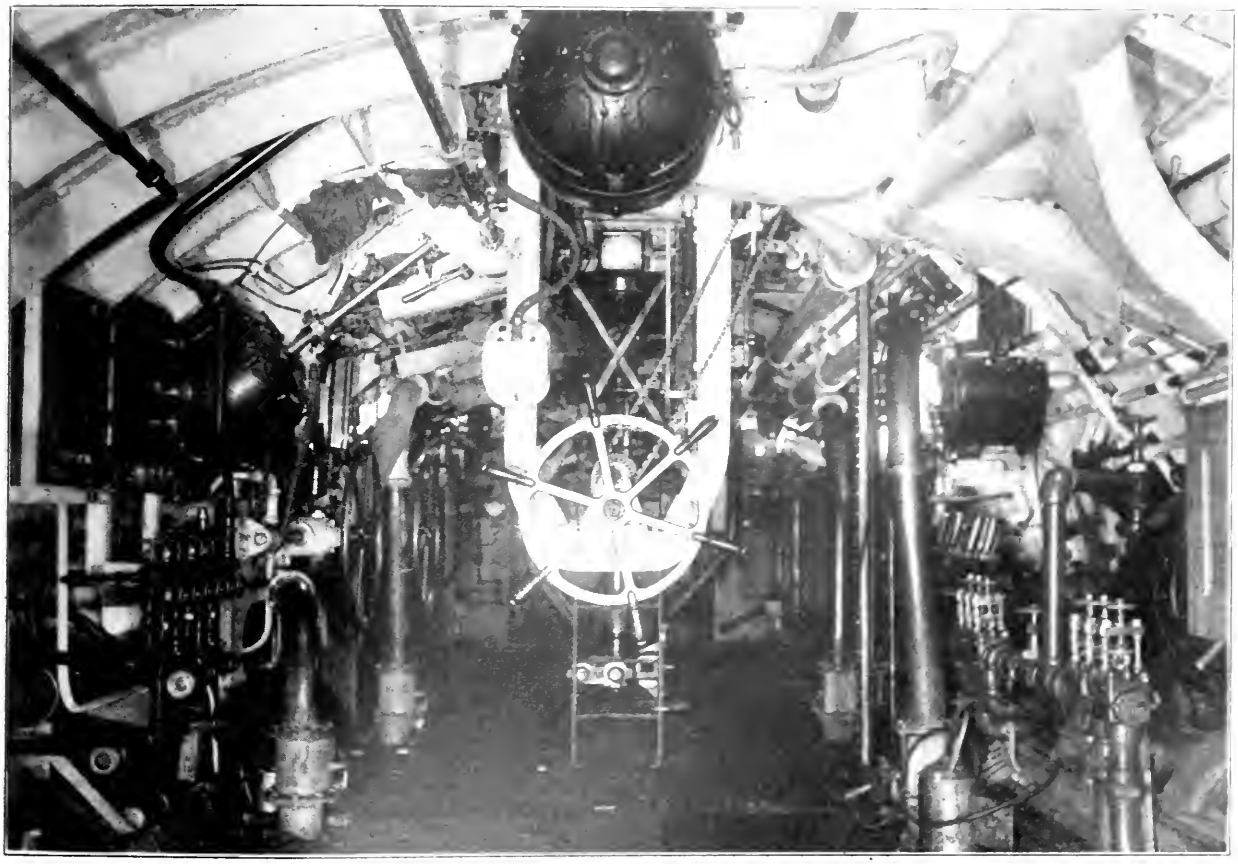

Fig. 12 From Amidships Looking Forward

Fig. 12 gives a good idea of the mass of equipment of a submarine, every part of the space being utilized. The picture is taken from amidships looking forward. In the center of the picture is shown the hand steering wheel. In general the steering is done by an electric motor, shown at the top of the picture. On the left is the air manifold,

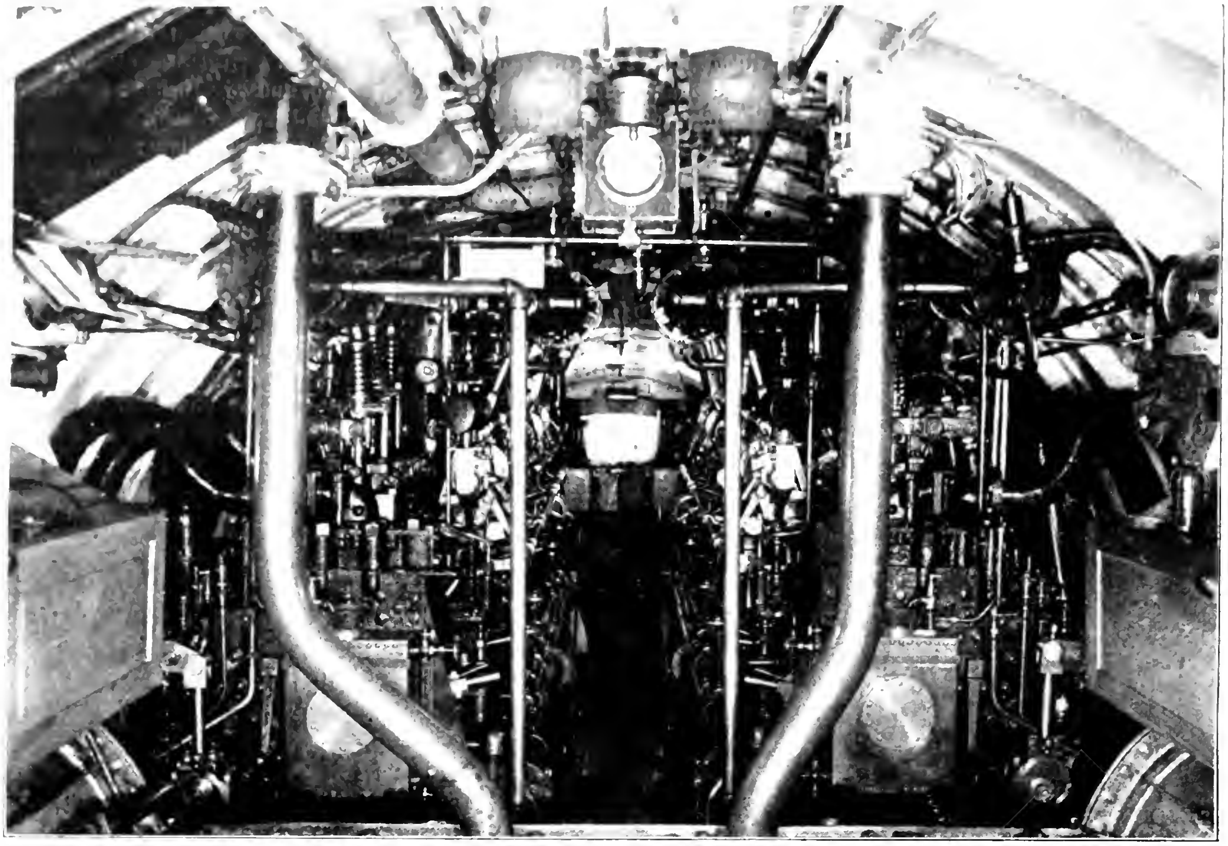

FIG. 13 FROM AMIDSHIPS LOOKING AFT

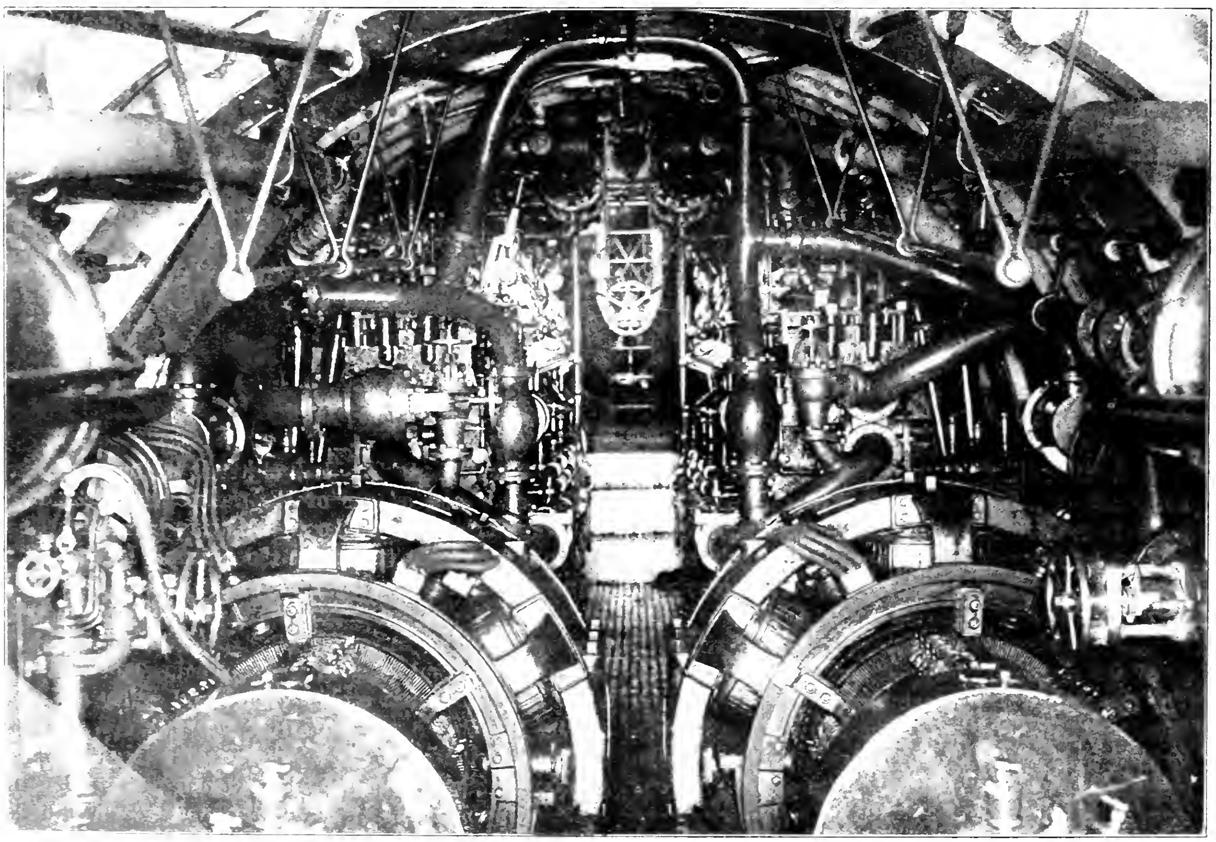

FIG. 14 FROM AFTER END LOOKING FORWARD

with valves [illegible] the high-pressure air. These valves connect [illegible] all the different tanks. By opening the valves to the [illegible] tanks, the water may be blown out in a short [illegible]. To the right is shown the water manifold which [illegible] the different tanks to the adjusting pump, also [illegible] large Kingston valves. Fig. 13 gives a view [illegible] and showing the main engines, and Fig. [illegible] looking forward, showing main motors [illegible].

One of the two engines for a submarine on the test stand is shown in Fig. 15. For many years the gasoline [illegible] was the best at our disposal, but as gasoline is a bad thing to handle in the confined space of a submarine, we were glad indeed when the Diesel heavy-oil engine became available for this work. The development of these engines was quite ad-

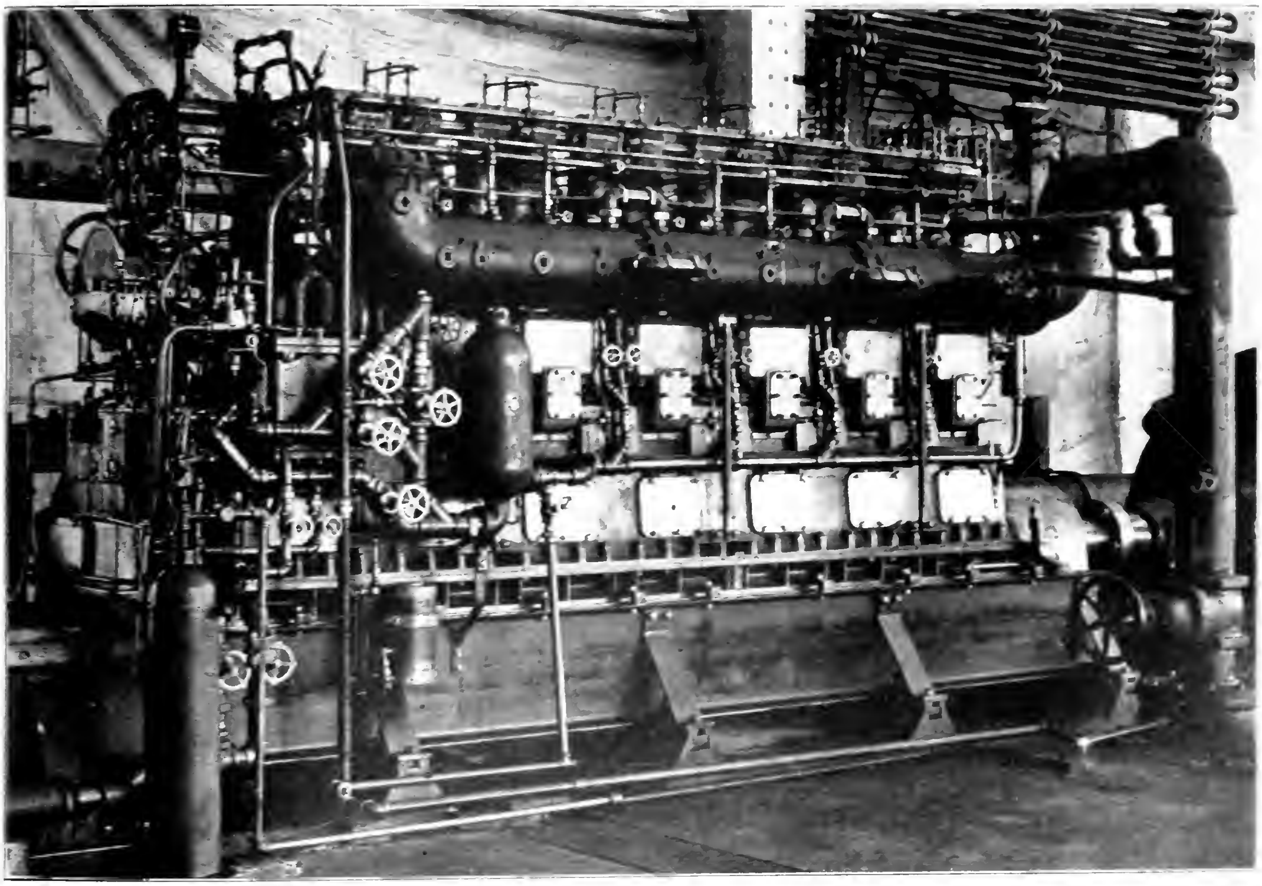

Fig. 16.—[illegible] Diesel Engine

vanced in Germany before [illegible] were built in this country. In [illegible] advance as rapidly as possible, all known [illegible] were examined by our engineers [illegible] engine built in Nuremberg [illegible]. Steps were immediately [illegible] country, and we were [illegible] submarines the best engine then developed. Many of these engines were built and are now in [illegible] our submarines. In the building and operating [illegible] and there were many things we [illegible] principal point being that they were very [illegible]. In consequence a new engine was designed—illustrated in Fig. 16. This is the type of engine used in many submarines recently built and has stood hard service with wonderfully good results. The change from gasoline to heavy oil has [illegible] interesting characteristic, that is, that with a given quantity of heavy oil twice the number of horsepower hours may be obtained as from a like quantity of gasoline. Thus with a boat having a given fuel tank capacity, double the radius of action [illegible] obtained when the change from gasoline to heavy oil is made. Another point is that heavy oil costs about one-fifth as much per gallon as gasoline; thus, for a given number of horsepower hours, the fuel of the Diesel engine costs but one-tenth that for the gasoline engine.

OPERATION OF SUBMARINES

The diving and behavior of the boat submerged is exceedingly interesting, and is shown in Figs. 17 to 23. In Fig. 17 we have the submarine stripped [illegible] deck [illegible] ready for submerged running. It takes but a few [illegible] take down the lines, [illegible] close [illegible] and [illegible] tanks. Fig. 18 shows the boat [illegible] trimmed down [illegible] for submerged running. The [illegible] when [illegible] is trimmed the boat [illegible] down [illegible] the diving rudders, exactly as the [illegible] steering rudder [illegible] a surface boat. If now the boat is started ahead with diving rudders kept at zero, the boat will rise as shown in Fig. 19. That is, the natural tendency of the boat is always to rise. If now the boat is given a diving rudder, the stern will rise, the bow will go down as shown in Fig. 20 and the boat will slide under. When this photograph was taken the boat was making a quick dive, and the angle of the boat is about five degrees. In general but three-degree angles are

ased in diving or rising, and for uniform running the boat angle will probably not change one degree. In Fig. 21 we see the boat well under, and in Fig. 22 she is running at a uniform depth. The actual distance of the boat from the camera when this picture was taken was but 91 yd., a very short distance over water. The control of depth even at high speed submerged is wonderfully accurate, runs being frequently made when for ten minutes at a stretch the depth will not change one foot.

If a submarine is resting on the surface and water is admitted to her tanks, she will gradually settle in the water. If care is exercised as the balancing point is reached the adjustment may be made so accurate that another gallon of water admitted to her tanks would cause the boat to sink. This is illustrated in Fig. 23, showing a boat weighing in the neighborhood of 100 tons thus evenly balanced. For the purpose of control of water in the tanks a small rotary pump is used, operated by a reversible electric motor. Thus water may be pumped either into or out of a tank. If when a boat is thus carefully balanced a little water is pumped into her tank, she will start to sink. Suppose after she has settled say to a depth of 40 ft. we pump out a little water. This will check her downward movement, and then she will start to rise. By watching the depth gage, and by careful control of the water by means of the pump, we may hold the boat suspended within a difference of depth of two feet. In general, after this test that of the automatic blow valve is made. This valve connects the high-pressure-air line with the main ballast tanks, and the control of the valve is by diaphragm in connection with the outside sea water. Thus if the pressure reaches too high a figure, the high-pressure air is automatically turned into the main ballast tanks. These tanks, it will be remembered, are entirely filled with water, whenever any is there, and therefore at such times the main Kingston valves are left open. The turning of the high-pressure air into these tanks is all the operation required to empty the tanks. In the test the automatic blow valve is set to some depth, say 50 ft., and the boat allowed to slowly sink. When this depth is reached the pressure outside operates the valve and some 75 tons of water are quickly blown out of the tanks. The boat immediately starts to rise, and in less than one minute will reach the surface, nearly jumping out of the water from the rapid rise. The automatic blow valve may be set for any depth that may be desired.

The subject of rescue of men from a sunken submarine seems to fascinate our inventors, as hardly a week passes but that some one comes forward with the same old method, that of a buoy of such a size that a man may get into it and then rise to the surface. It is not a question of getting a man to the surface—that is easily done, but of keeping him alive when he gets there. In this connection the statement should be made that there is only one cause that will prevent a submarine from coming to the surface, and that is a rupture of her hull. If now the hull is ruptured, the pressure of the outside sea is brought upon the men. In our respiration air is taken into the lungs, the oxygen taken up by the blood is used in the purifying of the blood, and a certain amount of nitrogen is retained in solution. This amount of nitrogen in solution in the blood is small at ordinary pressures, and in any case does no harm, for its quantity is a constant. If now a man is placed under heavy pressure, as would be the case if the hull of a submarine were ruptured say in 200 ft. of water, this pressure of about 100 lb. per sq. in. would cause the blood to absorb many times its normal quantity of nitrogen. This absorption takes place very rapidly, it requiring but a few minutes for the blood to become saturated to the point called for by the new pressure. If now a man so placed should enter a can buoy and rise to the outside air, the pressure would be quickly relieved and the excess nitrogen of the blood would be given off all through the system, given off in small bubbles which

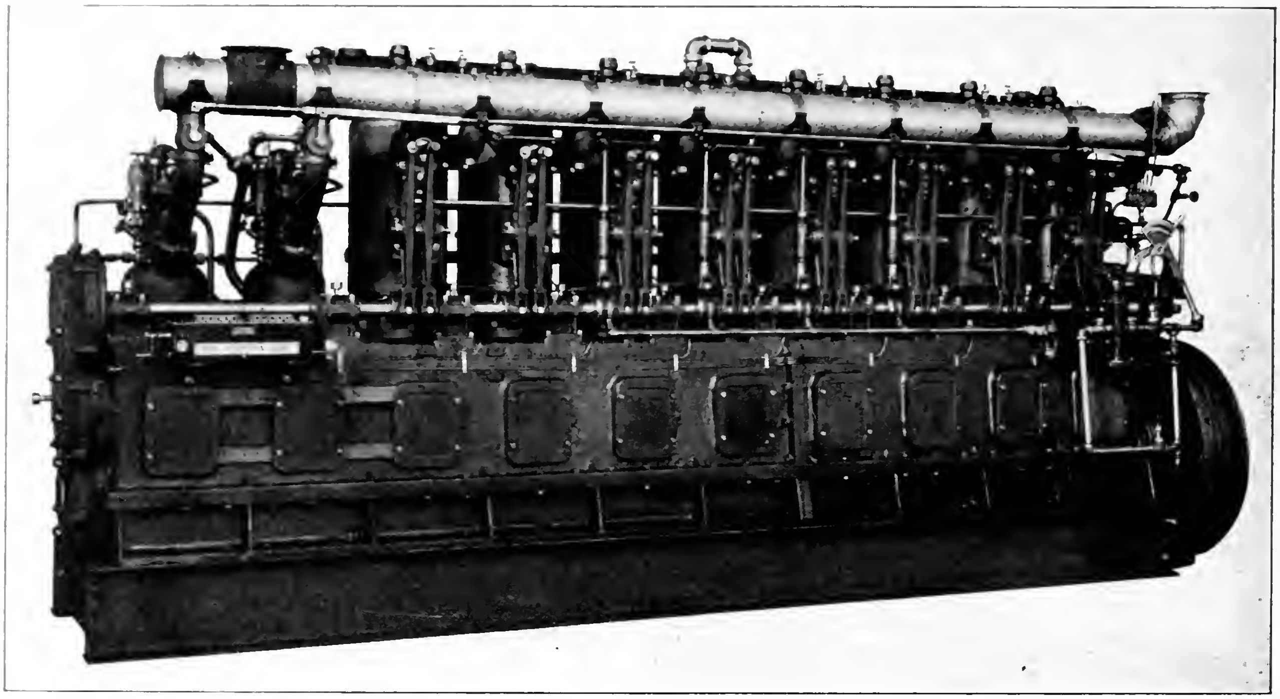

Fig. 16 240-hp. Four-Cycle Diesel Engine

would instantly stop all blood circulation and cause death. This action of the nitrogen is a familiar one to divers and all who are called upon to work under heavy air pressure. Thus it is not a question of the quick application of pressure, but the quick removal of that pressure. As an illustration, a few years ago a government diver went down some 280 ft. off New London. He took two minutes in going down, spent five minutes on the bottom, and then started for the surface. He came up a little way and then stopped, exercised his arms and legs thus encouraging activity of the blood in order to work the nitrogen off through his lungs. Then he would come up a little further and repeat the operation. The total time thus taken to reach the surface was one hour and thirty-five minutes, and even then as soon as he was taken out of his diving suit he was put into a recompression chamber so that the pressure might be still more slowly relieved. It will thus be seen how impossible it would be in the excitement of a wreck to go through any such procedure as outlined above.

Recent activities of submarines abroad have demonstrated the abilities of the boats, but generally the conditions are quite different from those that would pertain here in case we should be at war with one of the great foreign powers. Then the office of our submarines would be the breaking up of a blockade of our ports, or the preventing of an armed force from making a landing on our shores. Many times in naval maneuvers submarines have successfully attacked battleships, and where sufficient numbers of submarines are employed they may easily prevent a blockade by such ships. An interesting report was given some time ago of the breaking up of an entire expedition of a German army in its attempt to land at the south end of the Gulf of Riga, the work having been done entirely by two small submarines. If the report is true it shows wonderfully effective work by the submarines.

Engineering technological researches may be of great value to a country or to industries; but they inherently lack self-support. Any laboratory engaged in researches, the successful results of which are to be published, can only expect to be supported either by national institutions, by gifts, or by benevolent endowment. For this reason, although industrial researches are numerous and widespread, engineering researches are mainly restricted to universities, technical colleges and government laboratories.—*Science,* March 9, 1917.

THE MECHANICAL DEVELOPMENT OF AVIATION

By NEIL MACCOULL,[1] PITTSBURGH, PA.

The earliest systematic experiments with power-driven aeroplanes were started in 1889 by Sir Hiram Maxim, and from the data obtained he constructed a steam-driven twin propeller aeroplane in 1893. The span of the wings was 104 ft., which to this day is exceeded only by very few machines. The total wing area was over 6000 sq. ft., which is some twelve times as great as that of the average military aeroplane; but this was necessary because it was intended to fly at speeds of only 35 to 45 miles an hour. In the experiments with this machine, the running gear was provided with flanged wheels which ran on a straight level track of 9 ft. gage. Strong wooden guide rails of 3 x 9-in. Georgia pine were constructed along the track in such a way as to prevent the aeroplane from leaving it. This aeroplane not only lifted its own weight of 8000 lb. but also broke the stout plank guide rails which held it to the earth, and caused a wreck. But in spite of being able to support itself, it could not be called a successful aeroplane because its stability and airworthiness were never demonstrated in free flight. The power plant was the one part which was successful, and I doubt if there has ever been a steam plant of its size which weighed so little as 11 lb. per hp., including boiler, engines, condensers, pumps, and water supply. Each of the propellers, which were 17 ft. 10 in. in diameter, was direct-connected to a double-acting compound engine with cylinders of 5 and 8 in. bore and a stroke of 1 ft., high-pressure cut-off being at ¾ stroke and low-pressure at ⅝. These were constructed almost entirely of high-grade cast steel and weighed but 320 lb. each, complete. With a steam pressure of 320 lb. per sq. in. each developed 180 hp. at 375 r.p.m., a weight of only 1¾ lb. per hp. A safety valve discharged into the low-pressure cylinder, thus adding considerably to the power when there was an excess of steam. The boiler which supplied the steam for both these engines was constructed of a very large number of ⅜-in. copper tubes 1/50 in. thick, and had a heating surface of about 800 sq. ft., including the feedwater heater. Tubing such as this was quite a novelty in those days. A strong forced circulation of water was obtained by means of a spring-loaded valve in the boiler which held the feedwater at a pressure of 30 lb. per sq. in. in excess of the boiler pressure. This fall of 30 lb. in pressure acted upon the water in the tubes and forced it down through the large outside tubes. Although this boiler with the casing, dome, smokestack, and connections weighed less than 1000 lb., it supplied all the steam the engines could possibly use. The weight of the engines and boiler totaled 1640 lb. or about 4 1/3 lb. per hp. The condensers were made of very thin copper, the individual tubes being shaped somewhat like miniature aeroplane wings in section. By this means they were made to sustain more than their own weight when the aeroplane was traveling at its normal speed.

At almost the same time, Samuel Pierpont Langley, the real *father of aviation*, was learning the fundamentals of aerodynamics by means of models with rubber motors. After years of experimentation successful steam-driven models were constructed, and after nine years of strenuous work there was evolved a steam-driven model known as No. 5, which had a wing spread of 13 ft. and weighed 26 lb., complete. On May 6, 1896, this model was launched over the Potomac River with a steam pressure of 150 lb., and started directly ahead into the gentle breeze then blowing. After the lapse of one minute and twenty seconds, when at a height of 70 to 100 ft., the fuel was exhausted and the aeroplane gradually descended until it finally touched the water after a flight of over 3000 ft. This was the first time in history that a mechanical device had actually flown through the air under its own power. The engine of this model was a single-cylinder 1 5/16 by 2¾-in. double-acting type with piston valve, and drove the two propellers through bevel gears. It delivered about ¾ hp. and weighed barely 1 lb. The complete power plant, including engine, flash boiler, pumps, tanks, etc., weighed less than 8 lb., which is under 11 lb. per hp., an exceedingly creditable result.

Mr. Langley started his aeroplanes from a sort of catapult, in which the aeroplane was held to a carriage running on a track, and was released after traveling the length of the track under the impulse of coil springs. The man-carrying aeroplane, tried out in 1903, was launched from a similar device, and failed only on account of some accident which tripped the machine just as it was leaving the car and threw it into the water. This happened twice and caused so much ridicule in the press that Mr. Langley was unable to get any further financial aid. A few years after Mr. Langley's death, Glenn Curtiss repaired this aeroplane, and, by fitting it with pontoons so that it could rise from the water, was able to make a very pretty flight. It is interesting to recall that the Wright Brothers used in all their early experiments a launching device operated by falling weights, and a catapult similar to Langley's is now used for launching aeroplanes from battleships.

President McKinley became interested in the military possibilities of aircraft as a result of Langley's experiments, and in 1898 caused the Board of Ordnance and Fortification of the War Department to authorize the construction of a man-carrying aeroplane under Mr. Langley's direction. It was decided that the new machine should follow the general type of the models, because heart-rending difficulties experienced during the preceding eleven years had taught that even a slight departure from the type that had been successful might be very costly. The great difficulty was the power plant, which even today is the source of the greatest troubles with aeroplanes. Steam was seriously considered because of its success on the models, but the internal-combustion engine, just coming into prominence in automobiles, seemed to offer a more satisfactory solution. At that time flights of sufficient duration for the weight of fuel to become serious were not considered, otherwise little attention would have been given to steam, beause the most efficient plant yet constructed uses twice as much fuel as modern aeroplane engines, and when boilers and auxiliaries are included, are over twice as heavy as Langley's large internal-combustion engine made later. For this reason it is astonishing to hear rumors at present of responsible organizations contemplating the use of steam turbines for aeroplanes. The turbine itself can be made very light, but the weight saved over a reciprocating engine would be lost by the weight of the reduction gear required to drive the propeller at the proper speed.

[1] Westinghouse Machine Co.

Abstract of paper presented at a meeting of the Philadelphia Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, November 28, 1916.

In December, 1898, a contract was signed with an engine builder in New York City to supply a 12-hp. engine weighing not more than 100 lb., delivery to be made in 6½ *weeks.* The engine was completed before that time, but it was impossible to get it to deliver more than 4 hp. It was the first air-cooled revolving engine built, and the problems which developed were too much for the builder. A quarter-size model of this engine, when changed so as to have fixed cylinders with cooling ribs, performed excellently. In the meantime, European engine builders who were interviewed said that they did not care to undertake the work, and that they did not consider it possible to construct an engine of 12 hp. weighing less than 200 to 300 lb. If possible, they would already have done so, as they had had numerous inquiries for such engines. In spite of the discouragement, Charles Manly, assisting Mr. Langley, offered to undertake the construction of the required engine from the parts of the unsuccessful engines built in New York.

A five-cylinder, water-cooled radial engine (Fig. 1) was the outcome of his efforts. Each cylinder was drawn from a 3/16-in. steel plate by J. A. Stimmetz, and then machined inside and out, leaving a 1/16-in. shell. To this shell was brazed the valve chamber, which had been machined from a solid forging. The jackets, of sheet steel, only 0.020 in. thick, were brazed on by Mr. Manly himself, since no one else would undertake the work. In spite of the trouble involved, it was less difficult than to deposit copper jackets electrolytically, so undeveloped were these processes only fifteen years ago. To minimize the lubricating difficulties which might be experienced if the pistons were to bear directly against the steel cylinders, cast-iron liners 1/16 in. thick were shrunk in. Although engine builders had declared such construction impractical, if not impossible, no trouble was ever experienced with these liners, and they served their purpose admirably. The difficulties of attaching five connecting rods to one crankpin without sacrificing necessary bearing area were solved by the use of a "master rod"; one rod has a sleeve around the whole crankpin, as is usual with single cylinder engines, and the other four rods bear on the outside of this sleeve. In this way the small bearings between the four rods and the master rod receive none of the rubbing effect due to the rotation of the crankpin, except that of slipping a very short distance over the sleeve during each revolution, on account of the angularity of the rods. This construction was successful from the start and is now used in a slightly modified form in nearly all radial and revolving engines.

In order to get a reliable and equally hot spark in each cylinder, the scheme was originated of using one spark coil and vibrator for all cylinders, with a distributor to select the correct cylinder for each spark. All procurable spark plugs were very unreliable because of the frequency with which they became short-circuited with carbon; to correct this, a special plug was made. The pocket around the points which is now known to be so valuable, eliminated all this trouble. The intake valves were automatic, and the exhaust valves were operated from a central cam. This cam, which had two points 180 deg. apart, rotated at one-quarter engine speed in the opposite direction. The light weight of the whole valve mechanism is noteworthy. All parts were lubricated by oil cups. This engine was completed in December, 1901, and was given three 10-hr. runs while connected up to water dynamometers. At 950 r.p.m. 52.4 hp. was delivered, giving a weight of 2.37 lb. per hp., based on the stripped weight of the engine, which is 124 lb. The complete engine, including balance weights, ignition coil and batteries, carburetor, radiator, water and gasoline tanks, and all other accessories; and with radiator, water tank, and jackets filled with water, is only 3.65 lb. per hp. This is more than 20 per cent. lighter than present-day water-cooled engines.

Thus two Americans succeeded in producing the first man-carrying aeroplane which could support its own weight in stable flight; Samuel Langley produced the aeroplane, and Charles Manly produced the power plant. Those of us who blush with shame because our government possessed less than 50 military aeroplanes a few months ago while European countries were making daily use of tens of thousands, will do well to realize that this aeroplane was developed by the support of our own military authorities long before other governments did as much, and if it had not been for the ridicule of a hostile press and the sneers of a self-satisfied public, our government would have been the first to have possessed practical military aeroplanes. All this work of Langley's was terminated

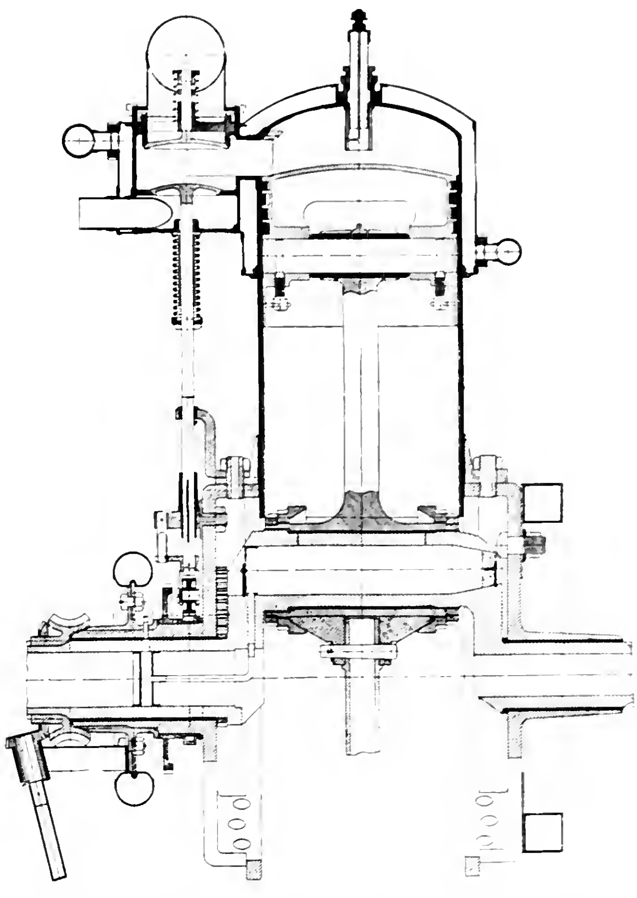

Fig. 1 Five-Cyl. Radial Engine (Fixed Cylinders) Built for Langley's Aeroplane in 1901. Cyls., 5 x 5½ in.

in 1903. Four years later Blériot constructed an aeroplane of the Langley type, and was able to make flights of a few hundred yards. The evolution of this machine resulted in the well-known Blériot type, now famous as the first to cross the English Channel.

Since then progress has been very rapid. Years elapsed from the time Langley solved the aerodynamic and mechanical details necessary for flight, before the Wright Brothers succeeded in flying for eleven minutes, and in 1914, only a few years later, the world's record for a non-stop flight was raised to 24 hr. and a distance of 1500 miles. This record still stands officially, for what has been done since the European War commenced is not accurately known by the public. Prèvost's speed record of 126 miles an hour made in

1915 still stands as official. An engineer just returned from Europe states that there are in France today 70,000 men wearing the uniform of the British Flying Corps, including pilots, mechanics, and other helpers. France and England together have about 14,000 licensed aviators, and Germany and Austria undoubtedly have as many. These 28,000 aviators do not include those of Russia and Italy. But even more astonishing is the statement made in the British House of Commons, that during the past two years Britain has spent $200,000,000 in aircraft. Another American engineer returning from Europe

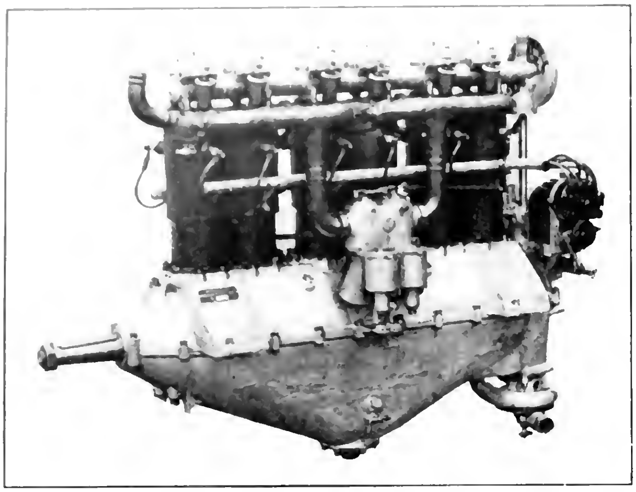

Fig. 2 The Famous Six-Cylinder Mercedes Engine Which Has Meant so Much to German Aviation

a year ago reported the sensations he experienced while flying several hundred miles in one of the Royal Flying Corps' giant triplanes which had a wing-spread of 135 ft., weighed just under 30,000 lb. and was propelled by over 1000 hp. in four water-cooled engines that it will always have value where speed and quick climbing are essentials and long flights are not desired, such as in defending cities and fortifications from enemy aircraft. The La Rhone, another engine of similar type, considerably improved, is now manufactured by the Gnome Company. The intake and exhaust valves are located in the cylinder heads and are both operated by a single rocker. The rocker for each cylinder is operated by a pull-and-push rod, which in turn is given motion by a large cam within the crankcase. This cam, which operates all push-and-pull rods for the nine cylinders, has five points, because it rotates at 9/10 engine speed and in the same direction as the cylinders. The ingenious valve-driving mechanisms of many of these revolving engines make a very interesting study.

The great majority of modern aeroplane engines are an outgrowth of conventional automobile practice. One of the most famous of this type is the German Mercedes (Fig. 2); many of the latest engines follow it in general design. The most noticeable feature is the method of operating the overhead valves by an overhead camshaft. While this general type of valve drive is now the prevailing style, it was an innovation when developed on the Mercedes. It follows the fundamental principles of accepted automobile practice throughout. In fact this very engine was used in racing automobiles and has given their drivers many enviable records. No very great effort has been taken to make this engine especially light except in the cylinder construction. The cylinders, which are in pairs, are built up from steel by welding the individual parts together. The strong point of these engines has always been their reliability rather than absence of weight. Their designers, instead of looking for radical departures from standard types, in order to save weight, were willing to apply minute attention to the development of recognized engineering principles in every infinitesimal detail. One of the characteristics which is now found on practically all aeroplane engines is the double car-

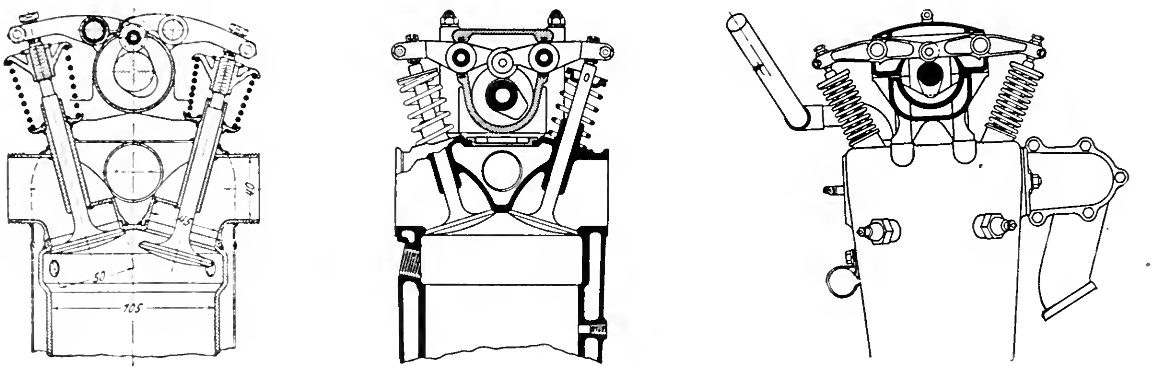

Fig. 3 Valve Mechanism of 3 Typical "Overhead Camshaft" Engines. Left, Mercedes; center, Hall Scott; right, Wisconsin

units. The world will be dumfounded at the status of the aeroplane when the veil of the censor is drawn after the war.

One of the first engines to spring into prominence during the early development of aviation was the Gnome. It is an air-cooled revolving type, somewhat resembling Mr. Langley's early though unsuccessful engine, and is an example of the most beautiful workmanship of which French mechanics are capable; which is one reason for the fact that even now it holds the world's altitude and speed records. Its outstanding faults are that it requires a great deal of fuel and skilled attention. Up to about 100 hp. it is so much lighter than the conventional

buretor for six cylinders. Surprising claims of gains in engine power, some over 20 per cent, are made for the use of two carburetors instead of one. Another feature is the use of a double ignition system; two independent magnetos and two sets of independent spark plugs to each cylinder. The deep oil sump with the oil pump at its lowest point is another characteristic. Practically no aeroplane engine is lubricated by splash, high-pressure lubrication being used exclusively. One of the chief points in which designers have a chance to show their ingenuity is in the combination of the camshaft drive with the drive for the magnetos and pumps. In this engine a

bevel gear on the crankshaft meshes with the bevel gears at the extremities of two vertical shafts, the upper driving the magnetos and camshaft through bevels, and the lower driving the centrifugal water pump at the lower extremity and in addition a horizontal shaft which in turn drives two oil pumps in the lowest part of the crankcase. It is a very neat arrangement.

From latest reports it seems that but few changes have been made in the designs of the Mercedes brought out since the European War commenced. The cylinders are increased in diameter from $4\frac{3}{4}$ to $5\frac{1}{2}$ in., so that the engine develops a maximum of 165 hp. instead of 100. They are now individual instead of in pairs but retain their welded-steel water jackets. The drive of the camshaft and auxiliaries has been modified so that the water pump is just below the camshaft bevels, the rotor being mounted on the vertical driveshaft which passes through it. This gives room for the oil pump where the water pump was formerly, and simplifies the drive of the former. These changes are design refinements which reduce the cost of manufacture and make the parts more accessible. The only departures in principle from former designs are the addition of cooling ribs on the bottom of the oil sump, and a set of decompression cams which are thrown into action by sliding the camshaft horizontally and make starting the engine by hand a fairly easy task, which is a matter of no small importance in an engine of this size.

One of the first American engines to follow the Mercedes is the Hall Scott. The cylinders, while individual as in the latest Mercedes, are cast with integral water jackets, giving a more rugged though heavier construction. The intake manifold and double-jet carburetor are water-and oil-jacketed, the oil jacketing not only warming the carburetor but cooling the oil. The valve mechanism of this engine is very nicely worked out. The camshaft housing is cast of aluminum and may be detached as a unit from the cylinders without disturbing the valve rockers. There are felt washers on each side of the rockers where they pass through the housing, and effective means are taken to lock the adjusting screws on the split end of the rockers. In all valve mechanisms of this type, the valves can be removed only by taking them out through the cylinders. The valve mechanism of this engine is shown in Fig. 3, in comparison with those of the Mercedes and Wisconsin.

Another six-cylinder engine of this general type is the Christofferson. The rocker arms are of different lengths as in the Mercedes, so that the valve has a 50 per cent greater lift than its cam. The whole valve mechanism is enclosed, which makes a very neat arrangement, and one that assures excellent lubrication of these parts, but it is doubtful if it is a wise policy to enclose the springs. It has been found very advantageous with many engines to allow the valve springs to project through the aeroplane hood so as to be sure that they will be well cooled. One of the most interesting features of this engine is a ring type of intake manifold, which allows each cylinder to draw its fuel mixture from two directions and would appear to give equal distribution to every cylinder without resorting to two carburetors. At the bottom of the crankcase is the oil radiator, which is beginning to be considered so valuable in preserving the proper lubrication of high-duty engines. The cylinders are made of steel and their jackets of aluminum, cast in pairs.

One of the well-known British engines is the Sunbeam. The 12-cylinder V-type rated at 220 hp. is the only L-head type of engine left on the aeroplane market now that the Sturtevant has been transformed. There are two carburetors for each row of cylinders, which are necessary to get the maximum power from the engine. It is of the high-speed type and runs normally at 2000 r.p.m., the propeller being driven at 1000 r.p.m. from the camshaft.

A new engine recently brought out by this company is a 12-cylinder V-type, rated at 320 hp. The L-head cylinders are abandoned, and the overhead valves are operated by 4 overhead camshafts. The valves are both mechanically opened and closed as in their racing automobiles, no springs being used.

For years the B. F. Sturtevant Co. has been a strong advocate of L-head cylinders, but has finally given in to the overhead type. The cylinders and heads are cast of aluminum and provided with steel liners and iron valve seats which are cast in

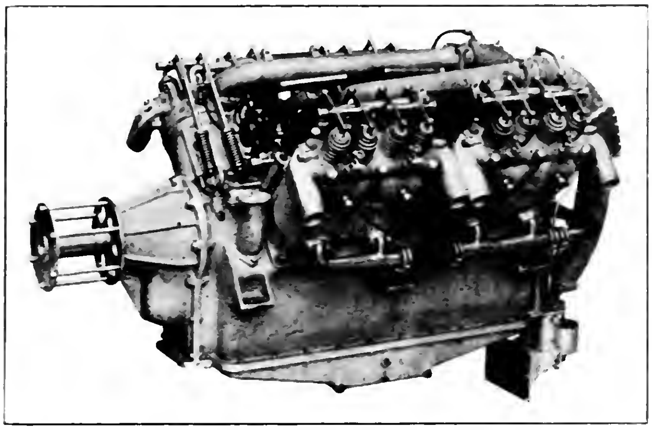

Fig. 4 The New Sturtevant 8-Cyl. "Aluminum" Engine with Overhead Valves and Geared Propeller Shaft. Normal Speed, 2000 r.p.m.; Cyls., $4 \times 5\frac{1}{2}$ in.; Rated at 140 hp.

the aluminum. The use of detachable cylinder heads is quite an innovation in the aeroplane world and shows a desire to make accessibility a stronger factor. As in the great majority of aeroplane and automobile racing engines, aluminum pistons are used, i. e., aluminum alloy, for pure aluminum is no more like its alloy than iron is like alloy steel, and in its unalloyed state would be absolutely worthless in this service. This engine is of the high-speed type with geared-down propeller, running normally at 2000 r.p.m. It is shown in Fig. 4.

The manufacturers of the new water-cooled Renault have supported the twelve-cylinder V-type with forced-draft air cooling for years, and it is interesting to note that in their new 200-hp. engine, Fig. 5, they have adopted water cooling. They have also dropped the high-speed feature with geared-down propeller shaft, and the valve mechanism with camshaft in the crankcase, which have been characteristic features of Renault aeroplane engines. The valve mechanism is now strikingly like that of the Mercedes. Use is made of two double carburetors and four six-cylinder magnetos. The connecting rods are of the type in which one rod is pinned to a boss on the rod opposite it. This is used on no other engine except the new Wisconsin "twelve," though it must have given good results, because Renault has used it for so many years.

A 300-hp. engine just brought out by the Knox Motors Co. shows an innovation in aeroplane-engine valve mechanisms. Not only are the rockers unusually compact because of being bell cranks, but each arm which operates the valves is forked so as to open two valves from a single cam. There are two intake and two exhaust valves to each cylinder, which feature

very considerably reduces the stresses in these parts on account of lower inertia forces for a given valve area and results in much greater reliability and longer life. The cylinders are cast of aluminum, with cast iron liners 1/8 in. thick. The pistons and the cylinder heads are of aluminum, the iron valve seats being cast integral. The oil pump at the bottom of the crankcase has a drive from bevel gears on the camshaft

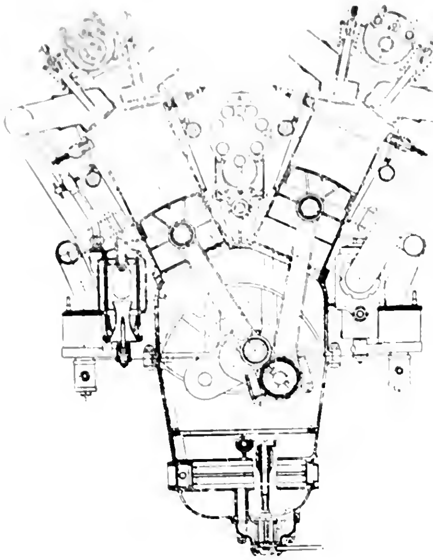

Fig. 5 12-Cylinder Water-Cooled Renault Engine. Cylinders, 4.9 x 5.9 in. 200 hp.

layshafts which are driven by spiral gears. This engine is shown in Fig. 6.

The Wisconsin engine (Fig. 7) has been brought out recently by the same company that manufactured the engines for the famous Stutz racing automobiles, and embodies many of their best features. It is another instance of the intimate relations existing between aeronautical and racing automobile engines. The cylinders, pistons, and crankcase are of aluminum. The cylinders have hardened-steel liners 1/16 in. thick and the iron valve seats are cast integral with the aluminum. The magnetos are driven by spiral gears. Nothing is contained in the lower part of the crankcase except the usual oil filters. The twelve-cylinder engine is made up of two sets of the cylinders and valve mechanisms of the six-cylinder model, and is rated at 280 hp. Instead of driving the camshaft by layshafts and bevel gears, two trains of spur gears are used, and four six-cylinder magnetos are arranged across the front of the engine. Provision is made on most of these large engines for mechanical or electric starters and the electric generators for searchlights and wireless sets which are often carried.

So far the development of the aeroplane power plant has been dealt with, but engines do not cover all the mechanical parts of modern aeroplanes by any means. Mechanical starters alone make quite a study, and besides compressed-air distributors and air engines, include even small gasoline engines of about 4 hp. which weigh but 23 lb. with their own magnetos and carburetors. Then there is a special gun of large bore for aeroplane use, which fires out of both ends at the same time in order to eliminate the recoil. There are many special instruments to indicate the speed, angle of incidence, drift, altitude, and other factors necessary for the navigation of an aeroplane. Mechanical stabilizers also have developed into quite a study by themselves. In the Sperry system there are four small gyroscopes driven by three-phase current, which maintain a constant horizontal reference plane, and motion of the aeroplane about this plane closes electrical contacts which

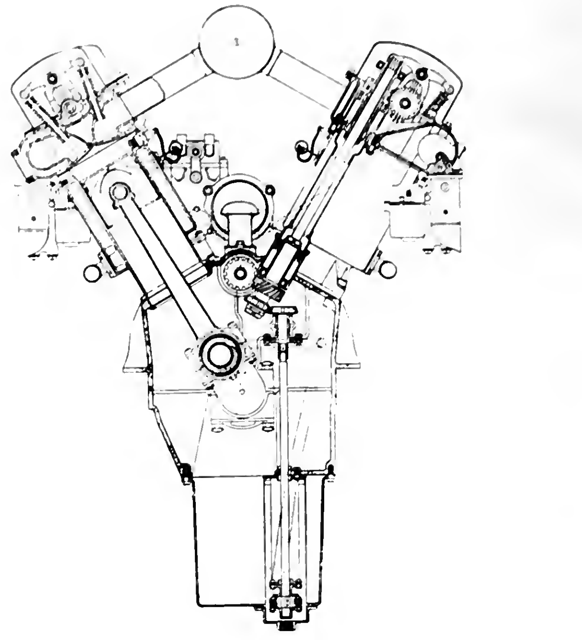

Fig. 6 12-Cylinder American Knox Engine. Cylinders 4¾ x 7 in. 300 hp.

operate clutches in the servo-motor. The windmill of the servo-motor, which is exposed to the relative motion of the air, is the source of power used in operating the controls. When the windmill reaches a predetermined speed, the blades fly outward, at the same time turning so as to reduce their

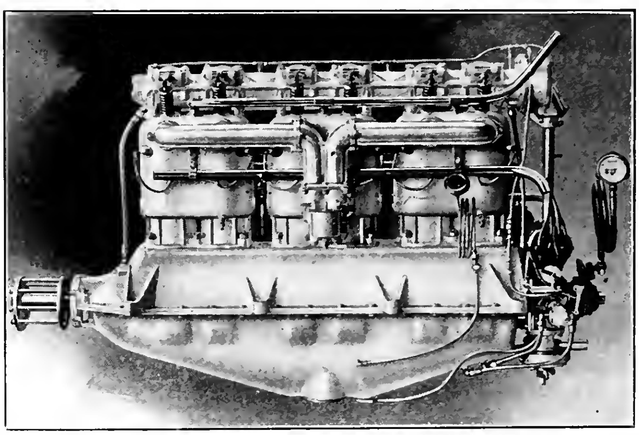

Fig. 7 Carburetor Side of the Wisconsin Engine. Cylinders, 5 x 6½ in.; Rating, 130 hp.

pitch, thus holding a constant speed. The magnetic clutches when energized connect the windmill to worm gearing, which drives the drums over which the control wires are wrapped. With this stabilizer it has been possible for the aviator to leave his controls and walk out on one of the wings while in full flight.

Descriptions of many mechanical parts of aeroplanes would not be expedient at this time because in many instances they would not be accurate even at the time they are read.

THE STEAM MOTOR CAR

By ABNER DOBLE,[1] DETROIT, MICH.

THE object of this paper is to recall the various objections to steam-driven motor vehicles which existed nine years ago when I first began my work on steam cars, and to tell of the steps to eliminate these objections.

The unsatisfactory points of the steam car were briefly, (1) low mileage on water, the average run on one supply of 35 gal. being 30 to 35 miles, although the Stanley is now securing about 200 miles; coincident with this necessity of frequently replenishing the water supply was (2) the formation of scale in the boiler, with a resultant drop in efficiency and added liability of burning the already extremely hot heating surface, which in turn necessitated the frequent cleaning of the boiler; (3) the toil and time involved in firing-up or lighting the main burner, which necessitated the use of matches and invariably required six or seven minutes or longer. The steam cars of eight or nine years ago also presented troubles of a less general nature; some had considerable difficulty with boiler leaks, some were too hot for comfort in summer, others carried their gasoline under high pressure and were altogether too easily ignited as a whole. Lastly, steam cars were very expensive to run, and their control and operation was a complex affair requiring intelligent and unfailing attention.

With the advent of the long-stroke, high-speed engine in Europe the internal-combustion motor came to be looked upon as the only practical power plant available, despite the admitted flexibility and smoothness of steam. I spent six years in building experimental steam-power plants and in experimenting. Late in 1913 we tried the combination of a fire-tube boiler with a honeycomb radiator to condense the exhaust steam. The results were truly startling. The car would run from 1000 to 1500 miles on one tank (24 gal.) of water. The effectiveness of the boiler was in no way lessened by the oil pumped into it.

The theory upon which we had worked was that in order to travel an adequate distance upon one supply of water, a honeycomb type of radiator must be employed to obtain the necessary cooling surface. The honeycomb radiator furnishes approximately six times the cooling surface of any other type of equal size. The reasons why this type had previously been deemed unavailable were the fact that the heavy molasses-like oil used in steam engines would clog up the extremely small radiator passages, and that the exhaust steam, particularly where a flash boiler was used, was liable to melt the soldered joints in the radiator. As far as I could find out, the use of a very heavy oil, especially where superheated steam was not employed, was a superstition. The presence of moisture in the steam goes a long way toward the proper lubrication of the cylinders and valves. In a steam-motor car little lubrication is required, as the piston speed is low at ordinary driving speeds, and the cylinder surface is cast iron, which is easy to lubricate.

In view of the foregoing it was determined to try ordinary gas-engine cylinder oil, and from the first it proved entirely satisfactory. To eliminate the possibility of melting solder in the radiator, we chose a fire-tube boiler. We realized that the presence of oil in the boiler would cause violent foaming, but believed that the high pressure used would eliminate trouble from this source. The normal steam pressure in the boiler was 600 lb., but as soon as the steam passed the throttle valve there was a large drop in pressure, sufficient to cause any water coming over from the boiler to pass into steam immediately.

Another reason why we did not use the customary heavy oil was because of the effect it would be certain to have upon the boiler. The action of the thin oil was all that could be desired. It immediately went into an intimate mixture with the water, due to the violent agitation and intimate contact. Agitation in the water tank was caused both by the motion of the car and by the fact that the return pipe from the base of the radiator entered the water tank very near the bottom. This also caused the water in the tank to act as a very effective supplementary condenser. The oil was accordingly regularly pumped into the boiler along with the water, and far from having a deleterious effect, really performed its most valuable functions in that part of the power plant. This oil is very thin at 420 deg. fahr., the approximate steam temperature at 600 lb. pressure, and the coating of oil, which forms over the entire inner surface of the boiler, is consequently so thin as to have a negligible effect upon the heat-transference conditions, and does not materially increase the liability of burning the heating surface.

As scale cannot adhere to a surface coated with oil, the interior of the boiler remains entirely free from incrustations of scale matter, and is likewise quite thoroughly protected from corrosion. The second function of the oil is to coat each particle of scale-forming material as it is thrown out of solution, thus preventing one particle from sticking to another in such a way as to form a body of sufficient size to clog some restricted passage. No large amount of scale-forming material is introduced into the system since but little make-up water is required, and all that remains in suspension until it reaches the water tank. The violent ebullition and constant flow of the medium toward the steam outlet causes the minute particles of scale to be carried along with the steam, so that the boiler and radiator are both kept free from deposits. The scale material finally reaches the water tank, where it either remains or continues to circulate through the system, without any apparent deleterious effect.

I have carefully examined the boiler and radiator of a car driven over forty thousand miles, and they were as clean or cleaner than when the car was built. I do not believe that there could be a more adequate proof of the entire effectiveness of the system. Lastly, the oil performs its normal function, being carried along with the steam in the form of minute globules, thus lubricating the throttle valve, cylinder walls and inlet valves.

DEVELOPMENT OF A STEAM GENERATOR

We next turned our attention to the development of a steam generator which would fill all our requirements. The fire-tube boiler, which had been successfully used in conjunction with our improved condensing system, possessed a number of the essential qualities we required; it held the temperature of the steam practically constant with no danger of sufficiently

[1] The General Engineering Co.

Presented at a meeting of the Cincinnati Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, February 15, 1917.

exhaust temperatures to melt soldered joints or effect an undesirable change in the lubricating oil. It always kept a large reserve of water heated to the steam temperature, which gave it steaming stability and admitted of great acceleration. The heat transference conditions caused it to be efficient, due to the extremely short distance, through which the gases of combustion radiated their heat to the tube walls.

On the other hand, it had its disadvantages: it was heavy and costly to manufacture, since it had to be wound with a mile of piano wire to minimize the potential danger present in a large diameter shell. It was liable to leaks, which might be caused either by overheating with low water or by oil working through the expanded joints where the tubes were fastened into the heads.

The flash type of boiler was out of the question, but it had certain good points which I intended to include in my steam generator. The direction of the water flow opposite to the flow of the gases of combustion was a great advantage, in that it allowed the water to extract, as far as possible, the last remaining thermal units. The all-steel construction, with its consequent freedom from leaks due to low water, was another very desirable feature. The water-tube boiler seemed to have little in its favor except safety due to the small diameter of the tubes, and the possibility of so constructing it as to have a good supply of water heated to approximately steam temperature. We had, however, already eliminated the possibility of scale settling in the boiler, so it seemed possible that we could use it as a basis upon which to combine the desirable characteristics of the other two types.

After much experimental work we finally worked out our present steam generator, similar in theory to the flash boiler, yet in appearance more like the water-tube boiler and having a water level in the evaporating zone. It consists of a number of identical sections of cold-drawn seamless steel tubing. Each section consists of an upper and lower header and sixteen vertical tubes. The vertical tubes are swaged at either end to half their diameter and are welded to the headers by the autogenous acetylene process, making each section in effect one piece of steel and actually stronger at the joints than the tubing itself. The generator is designed for a working pressure of 600 lb., and the safety valve is set for 1000 lb. Each section is tested to withstand 5000 lb., and ruptures only occur when the pressure is made to exceed 8000 lb. cold-water pressure. When this does occur, the rupture is invariably remote from the welds.

One third of these sections forms the economizer, the remaining sections being used for the actual generation of steam. They are placed very close together and completely encased by a $\frac{3}{4}$-in. wall of kieselguhr brick, which we have found excellent. This is held in place by a planished-iron jacket. Directly below the evaporating sections is the combustion chamber, and below the economizer is the exhaust for the gases of combustion. A bridge wall three fourths the height of the generator divides the two sets of sections. A manifold, through which water enters, connects the lower headers of the economizer sections. The water leaves by a similar manifold at the top and is led to a manifold connecting the lower headers of the evaporating sections. The steam leaves the upper headers and is conducted through a fourth manifold to the throttle valve.

Besides being absolutely free from any danger of explosion a boiler of this construction is cheap to manufacture, and any damaged section can either be easily and cheaply replaced, or isolated in a very few minutes by blanking it off until it can be replaced. The excellent heat-transference conditions due to the close and regular heating surfaces virtually duplicate those of a fire-tube boiler, while a large reserve of water close to steam temperature is always present. The progressive flow of the water counter to that of the gases, with no circulatory flow, and the all-steel construction show a distinct similarity to the flash type. Water is supplied to the boiler by a crank-driven pump, and the water level maintained about half way up the generator by an automatic regulator. If the water level falls below normal the regulator tube will fill with steam and its expansion closes a by-pass valve, thereby allowing water from the pump to enter the boiler. As soon as the level reaches normal, the regulator tube fills with water which has not been in circulation in the generator and is therefore comparatively cool. The regulator tube at once contracts, permitting the valve to open and all water to be by-passed back to the supply tank.

THE COMBUSTION SYSTEM

The most uncertain feature of the steam car, and one of its greatest disadvantages, was getting the burner properly ignited. Practically every steam car has used a bunsen burner of the vaporizing type. In order to insure sufficient mixture reaching the combustion space to ignite readily and continue burning, preheating was required to vaporize the fuel. Once the burner was going properly the vaporizer was heated by the fire, but when the car was not to be used for a time a supplementary burner was kept lighted to maintain the vaporizer heat and ignite the main burner when it was again necessary to generate steam.

On more modern steam cars acetylene gas has been used to heat the vaporizer. It considerably alleviated the difficulty, but meant an additional fuel tank to carry and replenish. After the vaporizer was hot the fuel valve was opened slightly, allowing the passage of only a very small amount of fuel until the burner itself had become thoroughly heated, and not until then could the fuel valve be left wide open without flooding the burner. When the fire was finally well started, steam was made quickly. With certain types of boiler sufficient pressure for starting could be generated in a minute and a half after the main burner was going. The chief problem of quick starting was therefore to eliminate the time required for lighting the main burner. The first real step we made in the right direction was to abandon entirely the former steam-car system and borrow a leaf from the book of gas-engine practice.

The idea was to use a spark plug for ignition, a carburetor for mixing the fuel and air, and an electrically driven blower to supply a forced draft. This worked fairly well as long as gasoline was used for starting, except for considerable precipitation of the fuel. We became more ambitious, however, and determined to make use of nothing but kerosene. The attainment of this more difficult goal required a large amount of experimental and laboratory work, but we finally determined that cold kerosene could invariably be ignited by an electric spark, if the following conditions were observed:

1 The kerosene had to be broken up mechanically into sufficiently small particles to insure a rise in temperature past the point of ignition during the time in which they absorbed heat from the spark

2 The spark had to occur close to the atomizing nozzle at a point where the resultant fog was sufficiently dense to insure one group of kerosene particles invariably igniting the rest

3 The velocity of the fuel particles had to be low enough to permit them to absorb sufficient heat from the spark to raise their temperature beyond the ignition point

4 It was essential that the mixture be much richer in the vicinity of the electric spark than that which would provide the most efficient combustion. In the latter connecnection we also found that in order to secure complete combustion of a large amount of fuel in a small space, it was necessary to utilize a combustion chamber made of a highly refractory material designed to attain a very high temperature.

To meet these conditions we developed the apparatus which we now use. The electric current is supplied primarily by a generator driven by the main driving gear. This charges a storage battery, which furnishes the ignition spark and drives the motor blower. As there is but comparatively little demand upon the ignition, we can afford to use a primary current of high amperage and accordingly secure an unusually hot spark. The kerosene is fed under low air pressure to a float chamber similar to that of a gasoline carburetor but of special design. A jet fed from the float chamber projects into a venturi tube perpendicular to the center line of the tube. The level, when the apparatus is not in operation, is somewhat below the mouth of the jet. A multivane blower driven by a small electric motor forces air through the venturi tube into the combustion chamber. The passage of the air creates a vacuum of several inches in the fuel jet, causing the kerosene to pass the spark plug as a fog of very finely atomized particles. The tube widens considerably before the point where the spark occurs, thereby appreciably diminishing the velocity of these particles.

As soon as ignition occurs, the heat of the fire causes a bi-metal switch to break the spark circuit, and the fresh fuel continues to be ignited by that which is already burning. When the steam pressure reaches 600 lb. it breaks the motor-blower circuit and fuel ceases to enter the combustion chamber. As soon as the pressure decreases to 550 lb. the circuit is remade and the spark once more ignites the fuel. This arrangement maintains the pressure in the generator virtually at normal without any attention on the part of the driver. Another motor-blower circuit breaker is used as a safeguard against the possibility of low water in the generator due to lack of water in the supply tank. In this case the breaking of the circuit depends upon the expansion and consequent elongation of the lower header of one of the generator sections when it becomes overheated.

This generator was rated at 75 hp., was 32 in. long, 22 in. wide and 28 in. high. The heating surface was slightly in excess of 150 sq. ft. When ignition took place the water in the generator was at 66 deg. fahr., but reached 212 deg. in forty seconds; in eighty seconds the pressure was 100 lb.; it reached normal, or 600 lb., two minutes and fifty seconds after the switch was turned, the increase from 500 to 600 lb. requiring just ten seconds. In order to maintain a full head of steam, 600 lb., it is only necessary for the combustion system to operate seven seconds in every twenty minutes. This applies when the car is standing where the surrounding temperature is about 60 deg. fahr.

THE ENGINE

In designing the engine my chief concern was to provide ample dimensions of the working parts in order to insure continued operation under maximum conditions of load. Although the compound engine may provide for high expansion, it is not desirable for use in motor cars, as the ratio of the cylinder volumes has to be carefully determined in relation to the probable loads, speeds and steam-chest pressures. In the steam car these conditions vary so widely that it was necessary to use the single-expansion engine.

I employed the uniflow principle, because I wished to secure high expansion with a simple, noiseless valve gear and one valve per cylinder. The inlet valves are placed on top of the cylinders. They are of the slide type, and are so constructed as to lift off their seats if the compression at any time exceeds the steam-chest pressure. Another reason for the uniflow was the fact that it makes unnecessary the use of superheated steam, as the thermal conditions in the uniflow cylinder approach the ideal. All troubles caused by superheated steam are therefore absent, and but little cylinder lubrication is necessary. The exhaust is through ports uncovered by the piston at the end of its stroke. With this arrangement it is possible to secure cut-off as early as 10 per cent of the stroke. The inlet valves are actuated by a simplified form of the Joy valve gear, thus dispensing with eccentrics and making possible a one-piece crankshaft. It differs from the Joy in that it dispenses with the connecting and anchor links, and has a straight instead of a curved rocker guide.

This gear operates the 1/4 cut-off, which is used for all ordinary running, with perfect accuracy, and the slight variation at 5/8 cut-off, which is used for starting or heavy pulling, and at 1/8, used for high speed or economy, is not noticeable in the running of the car. To provide against water in the cylinders or a leaky throttle valve, a small piston valve is placed on the lower side of the cylinders. This valve is normally held open by a spring. It is connected to the four clearance spaces of the cylinders, and any water or steam not under sufficient pressure to actuate this valve passes through it to the atmosphere. As soon, however, as any steam under an appreciable pressure reaches it, the pressure will force down the piston and close the valve. The engine is geared to the rear axle in the ratio 47:49, or virtually one to one; yet can produce sufficient torque to slip the driving wheels on dry pavement. On account of the low engine speed an elaborate system of lubrication for the engine mechanism is entirely unnecessary.

I will sum up the chief advantages of such a steam-power plant for motor-vehicle service.

1 Torque range of 100 per cent with a maximum torque available at zero speed; change-gear mechanisms and clutch therefore unnecessary

2 Mean effective pressure (and equivalent drawbar pull) always under control of the operator; variable by throttle and cut-off from zero to maximum, a maximum limited only by the tractive capacity of the rear wheels

3 Utmost mechanical simplicity with not over twenty-four moving parts in the entire car and only eleven in the engine

4 Smooth and quiet operation, due to low engine speed and to location of the engine

5 Low manufacturing cost, owing to simplicity of construction and lack of "fussy" work in production

6 Entire absence of lubrication troubles; no contamination of crankcase oil by kerosene, gasoline, water, road dust, or carbon

7 Low fuel cost per mile.

In connection with this last point, some very brief statistics may prove of interest. As a basis of comparison, we selected three well-known gas cars, the first being a six-cylinder car

weighs [illegible] 2400 lb. and developing a maximum of about [illegible] hp.; the second weighs 2700 lb., has six cylinders, and [illegible] develops [illegible] hp.; the third, a twelve, weighs 4400 lb., and develops 80 hp. Our steam car has a generator rated at [illegible] hp., and weighs 3400 lb.

The four cars may be known as A, B, C, and D, and the results at [illegible] on a level road were as follows: A delivered [illegible] hp. at the engine, 12.[illegible] hp. at the rear tires, and traveled [illegible] miles per gallon of gasoline. *B* showed 14.3 hp. at the engine, 10.6 hp. at the wheels, and ran 15.4 miles per gallon of gasoline. *C* developed 36.1 hp. at the motor, 29 hp. at the wheels, and obtained 9.5 miles to the gallon. *D*, the steam car, at 10 m.p.h. develops 13 hp. at the engine, 10 hp. at the rear tires, and secures 11.1 miles per gallon of kerosene.

With gasoline at twenty cents and kerosene only eight cents per gallon in Detroit, there appears to be a considerable balance in favor of the steam car, but it is at the more normal driving speed of twenty miles per hour that the best economy showing is made.

A, a light car well known for its fuel economy, at 20 miles per hour ran 31.5 miles on one gallon of gasoline; *B*, 22.7 miles; *C*, 11.8 miles; and *D*, 17.3 miles on a gallon of kerosene.

REDUCING FRICTION BY AUTOMATIC LUBRICATION

By J. Wm. PETERSON, MILWAUKEE, WIS.

Member of the Society

It is my vocation to make things run smoothly, and as has been so aptly said: "Blessed are they that remove friction, that make the courses of life smooth and the intercourse of men gentle." It is not work that kills off so many of our prominent business men before they have reached their allotted three score and ten, it is worry. Revolution does not destroy machinery, it is worn out by friction, which is the worry of work.

Friction is the resistance produced by two bodies coming in contact in a sliding or rolling motion. The product of this resistance or friction is a rise in temperature. You can warm your hands by briskly rubbing them together. Now, put some oil between your hands, and you can rub all day without producing enough heat to feel it. There is just this much difference between properly and poorly lubricated bearings.

It has always seemed to me that friction and its natural antidote, lubrication, have not received as much study from engineers as their importance would warrant. For instance, in a recent book by Archbutt and Deeley,[1] authorities on lubrication, one finds the remarkable statement that more than one half of the 10,000,000 hp. developed in Great Britain is expended in overcoming friction, and that a considerable portion of this wasted power is due to faulty lubrication; and again, in Professor Thurston's[2] classic treatise on Friction and Lost Work we find the statement: "It may probably be fairly estimated that one half the power expended in the average case, whether in mill or workshop, is wasted in lost work, being consumed in overcoming the friction of lubricated surfaces."

While the two statements quoted are general, they are based upon the experience of two well-known authorities. With these figures in mind, when we purchase new machinery let us not be so foolish as to quibble for that fraction of a per cent in efficiency guaranteed for our new engines or machines, and pass lightly over the question of lubrication or make no mention of it at all in our specifications. Let us not lose sight of the fact that the efficiency of an expensive machine may, after a few months of service, become lower than that of a less expensive machine, simply through lack of an efficient system of lubrication. A prominent dealer in second-hand machinery has remarked that in the purchase of any second-hand apparatus he always looks first at the bearings, for their condition largely determines the value of the machine in his eyes. In other words, if the machine has a good system of lubrication, the second-hand value is considerably higher.

Probably the reason friction losses are not so forcibly impressed upon us is because of their insidious nature. We can see leaks in the steam piping and repair them, our CO_2 recorder instantly shows improper methods of firing boilers, a thermometer tells us when our flue gases are too hot or our feedwater is too cold, and our voltmeters indicate the voltage of our electric generators, so that we can correct defects; but the losses caused by friction are not so obvious nor so easily measured. It is only when it becomes excessive—when the bearing becomes decidedly overheated or the babbitt starts to run out—that we become impressed as to the enormous power-consuming properties of friction.

The antidote for friction is scientific lubrication, or the application of a lubricant of the right kind at the right place and in the right quantities. It is the proper valuation of the last three items that gives us the most trouble and usually requires the services of a competent lubrication engineer. In order to give these points brief consideration, I will divide lubrication into two parts, first, interior or cylinder lubrication, which is delivering oil into cylinders and valves against the pressure of the steam, air or gas; and second, bearing lubrication.

CYLINDER LUBRICATION

This problem places us between the two horns of a dilemma. We know that the more oil we use, the smaller will be the amount of power consumed by friction, but we know also that most of the oil which is mixed with the steam going into the cylinder passes out with the exhaust and is forever lost. Up to the present time no good commercial system has been devised for separating oil from exhaust steam or the condensate and rendering it again suitable as a lubricant for cylinders. Of course a certain amount of oil can be removed by line separators, etc., but this is usually mixed with so much water and is so thoroughly emulsified that it is not suitable for further cylinder lubrication. The object in cylinder lubrication is to secure the highest degree of lubrication with the smallest amount of oil.

[1] Lubrication and Lubricants, 3d ed., p. 50.

[2] 7th ed., p. 12.

Presented at a meeting of the Milwaukee Section of The American Society of Mechanical Engineers, December 20, 1916.

Another reason for keeping the amount of oil as low as possible is that as it is impractical to remove it from the condensate, and a large proportion of the oil finds its way into the boilers and makes trouble, for oil is quite an efficient heat insulator. Wm. Parker, Engineer-in-Chief of Lloyd's Registry, found not long ago that by painting an open steel dish with three or four coats of greasy deposit taken from the bottom of a boiler and mixed with cylinder oil, it was possible to burn the dish before the water in it boiled. This might be called a side line of lubrication, but lubrication engineers have to take it into consideration.

Within the memory of the youngest engineer cylinder lubrication has gone through many changes. First, suet or tallow was injected through a small hole in the cylinder every time the engineer happened to think of it. Next, grease cups were used, grease being supposed to be reduced to a liquid and flow into the steam chest, lubricating the valves and cylinders; but as the grease was usually cooked out of the cups, it went everywhere except where needed. Next came the hydrostatic lubricator, in which two or three feet of water pressure is used to force the oil into the steam. The last and most important step was the general adoption of the mechanically driven force-feed lubricator, in which the oil is positively, and at regular intervals, forced into the cylinders by means of pumps.

Most plants have adopted the system of force-feed lubrication for the main power units, but there are many depending upon more or less antiquated methods for supplying cylinder oil to their auxiliaries, such as pumps. Many engineers do not consider the auxiliaries of enough importance to warrant the refinement of automatic lubrication, but as auxiliaries are usually located in the basement, boiler room, or other out-of-the-way places, where they do not receive as much attention as the main units, automatic lubrication of such machines is of at least as much importance as that of the main units. The amount of power consumed by the auxiliaries, compared with the main units, clearly shows that lubrication of the former must be carefully considered.

For illustration, take one of the largest railway houses in the country. The areas of the rubbing surfaces of the main units in this plant amount in all to about 1,507 sq. ft., while those of the steam and air ends of the auxiliaries, air compressors, vacuum pumps, etc., total about 530 sq. ft.; thus there is one-third as much rubbing surface in the auxiliaries as there is in the main units, and as some of the auxiliaries are automatically started and stopped without supervision, it is evident that they should not only be supplied with a good system of lubrication but also with one which will start and stop automatically with the machines to which it is attached.

The power consumption of auxiliaries is more striking in smaller plants than in large ones. For instance, in the Marbridge Building 34th Street and Broadway, only 50 per cent of the power produced is used by the main generating units, the remainder being consumed in elevator pumps, blower engines, vacuum boiler feed, house pumps, air compressors, etc. In the power plant of a modern apartment house in New York City, two-thirds of the total power is consumed in the main units, the other third being used for refrigerating machines, boiler feed and house pumps, vacuum cleaning systems, sewerage pumps, etc. These are only a few examples, but there are many plants where, even though the main units are properly lubricated, the cost of lubrication could be greatly reduced and the plant efficiency improved if the auxiliaries were equipped with an efficient system of lubrication.

Properly designed force-feed lubricators deliver a predetermined amount of oil and the delivery is not affected by changes in temperature or the viscosity of the oil. They are much cleaner and neater to handle than hydrostatic lubricators and can be filled while in operation or connected up to a central system of supply, and will effect a saving in oil of at least 50 per cent.

BEARING LUBRICATION

The problem of adequately lubricating bearings is entirely different. In the old days the engine had a few holes and the engineer had to treat it to a dose of oil on frequent visits; in some instances bearings were provided with grease cups, and instead of a dose of oil he would, on his regular rounds, give these cups an extra twist. Nothing similar to this is now seen in the modern power plant. Economical lubrication requires the installation of modern scientific apparatus which will automatically apply the oil in a manner that will do the most good. Poor lubrication increases wear and tear, reduces the life of machinery, and wastes a large amount of power by friction, resulting in increased fuel consumption.

The only economical method of lubricating bearings consists in supplying as much oil as the bearings will take and of collecting, filtering, and using it over and over again. In passing through the bearings the oil takes up small pieces of metal removed from the bearings by friction, dust, etc., also water from condensed steam, which has leaked past the stuffing boxes. If solid matter and water are properly removed from the oil, it is in a condition to be used over again; therefore the crux of a good automatic system of lubrication is the filter, wherein the oil is restored to its original pure and clean state. An engine or machine equipped with an efficient system of continuous lubrication feeding a stream of oil to all bearing surfaces will run much cooler, wear longer and render the necessity of keying up less frequent than is the case where lubrication is provided by oil cups feeding drop by drop.

In the power plant of a shoe factory the engine-room log shows that before the adoption of continuous stream lubrication it was necessary to key up the pins and [illegible] once every two weeks, whereas since the oiling system was installed, keying up is only necessary every six to eight weeks. One of the engines in this plant, a 200-hp. Corliss engine, is equipped with an individual oiling and filtering system, and the make-up oil only amounts to two gallons per month. A further illustration of what can be accomplished with a properly designed automatic system of bearing lubrication is furnished by one of the largest public-service plants in the country, where 30,000,000 kw. are generated each month. The total amount of oil consumed for all the main generating units and their auxiliaries amounts to only 300 gal. [illegible] and in another plant the actual cost of cylinder and bearing lubrication amounts to only two cents per 1000 [illegible]

PLANT EFFICIENCY

The work done by a steam engine is necessarily divided into three parts: that done against the outside load, which alone is the useful work; that done against the back pressure in the cylinders; and that done against other resistances, the most important of which is friction. Work is also done at the beginning of each stroke in overcoming the inertia of the moving parts, but in a properly designed engine most of this should be restored to the engine before the end of each

[illegible] In the modern type of engines the mechanical efficiency is very high. In tests of ten new engines of different makes—four simple, four compound, one triple expansion and one quadruple expansion—the mechanical efficiency ran from 9[illegible] per cent to 97 per cent.

In engines not so modern in design and which have been running for some time, the mechanical efficiency may be surprisingly low. In one of fifteen engines tested of this class, which have been operating from ten to twenty years, the mechanical efficiency averaged about 70 per cent. In one case it ran as low as 60 per cent. If the mechanical efficiency is 70 per cent, the recoverable loss would be at least 20 per cent. Take a plant of, say, 1000 hp. The cost of producing a horsepower per year is about \$30. A loss of 20 per cent would be 200 hp. at \$30 per year, or \$6,000.

The values for the mechanical efficiencies of steam engines are about as follows: 95 to 98 per cent, rare and unusually high; 90 to 95 per cent, usual good practice; below 80 per-cent, decidedly low. Experiments on distribution of friction show that the greatest loss, amounting to one-third or one-half of the total friction, occurs in the main bearings; the next important loss is that of the piston and piston rod, amounting to about 21 per cent of the total friction. Of this amount $6\frac{1}{2}$ per cent is chargeable to the friction of the piston and rings against the cylinder walls, and about 14 per cent to the stuffing box of the piston rod, leaving 1.7 per cent chargeable to unaccountable losses. The losses due to friction of the working parts of an engine include considerably more than the mere loss of power, namely, the depreciation resulting from wear of bearings, guides, and other rubbing surfaces, and the expense arising from accidents traceable to excessive friction.

DESIGNING LUBRICATION SYSTEMS

There has always been a great deal of guesswork, mystery, and secrecy on the part of manufacturers in regard to the general design and installation of automatic bearing-lubrication systems for power-plant machinery. The lack of general information on this subject has resulted in the installation of many unreliable oiling systems not really suited to conditions existing. The requirements of an efficient lubricating system are:

1 A stream of clean oil supplied continuously at just the points where needed.
2 A filter which will thoroughly remove all dirt, small particles of metal, and entrained water, and properly cool the oil.
3 The system should be automatic in its operation and absolutely reliable.

One sometimes hears the statement made that oil becomes worn out through use. This is not the case, as has been amply proved by extensive tests made by several eminent authorities. There may be some slight increase in its specific gravity after it has been used continually, owing to the fact that by increase of temperature some of the more volatile oils are driven off and small amounts of cylinder oil used for lubricating the piston rods, etc., become mixed with the bearing oil; however, the heavier oil is still as good as ever, if properly treated. In some cases the mixture of cylinder oil with the bearing oil, which gets into the system from the piston-rod lubrication, causes serious complications on account of the small percentage of animal fat necessary in the cylinder oil. This in time causes the oil to become emulsified and entirely unsuitable for circulating. To remedy this trouble, there are two alternatives; the first is to dam off the space below the piston-rod stuffing box between the cylinder and the guide barrel so that the cylinder oil dropping from the rod is carried off through the bonnet drips and does not become mixed with the bearing oil; the second is to install a wiping device on the piston rod and lubricate it with bearing oil. I know that a great many engineers believe that only cylinder oil is suitable for lubricating piston-rod stuffing boxes, but we have had very good success in several instances by applying regular bearing oil in this manner.

The lubrication engineer has three alternatives to work upon in the design of a scientific system: he may install a central oiling system in which the main supply of oil is stored at one point and conveyed to the bearings of the various power units and auxiliaries by means of main feed and branch pipes to each machine; or he may make each individual engine, pump, air compressor, etc., a unit by itself, and supply it with its own oiling and filtering system; or he may provide a combination of the two by providing one lubricating system to take care of a group of machines.

In the application of the first system it is necessary to install a large part of the apparatus in duplicate in order absolutely to insure continued operation of the plant. The amount of duplication depends a good deal upon the arrangement of the plant, the susceptibility of the various parts to injury, the value of continued operation and also the ideas of the designing engineer.

To insure absolutely reliable lubrication, many plants are now installing individual oiling and filtering systems, so that each unit, from the smallest auxiliaries to the largest power unit, is equipped entirely independently of all other units in the plant. Practically everything necessary for these individual oiling systems is above the engine-room floor and therefore always in sight and under the care of the engineer or attendant.

The so-called splash system used on several makes of high-speed engines has many disadvantages. Usually the engine frame forms an oil reservoir, and the crank dipping into the oil at every revolution throws it out on the rubbing surfaces. It soon becomes saturated with small particles of metal and is entirely unsuited for use over and over again between the rubbing surfaces; furthermore, the oil, being at the high temperature of the engine frame, has practically no ability to carry off heat which may be generated in the bearings, and finally on some engines the steam leaking past the piston-rod packing and condensing in the oil reservoir soon mixes with the oil to such an extent that an emulsion is formed, which has practically no lubricating value. The proper lubrication of engines equipped with the splash system can be easily accomplished by connecting an oil supply line into the reservoir of the splash system and a dirty-oil overflow arranged so that a predetermined level of oil is maintained in the reservoir; thus the dirty oil passes out through the overflow at the same rate at which clean oil is delivered into the reservoir. In this way continuous circulation of oil is maintained and good reliable lubrication is insured. Real bearing-lubrication economy is possible only when

1 Every bearing is continually supplied with a stream of clean oil so that the rubbing surfaces float past each other on a film of oil instead of coming into metallic contact, reducing cost of producing power.
2 When the oil is automatically collected, filtered, purified for use over and over again, reducing cost of attendance and oil.

PROBABLE REQUIREMENTS IN MACHINE TOOLS

A Discussion of Means for Their Fulfilment, and a Description of an Automatic Tool-Feeding Mechanism in Which the Feed is Governed by the Driving Torque

By A. M. SOSA,[1] CINCINNATI, O.

OUR observation of the progress made in the construction of machine tools in the last twenty years shows that the development of machine tools has been accomplished by the natural process of producing or designing mechanisms to meet the requirements that were brought forth in the course of the work, and which requirements may well be divided in two classes. To the first belong those that are due to new conditions created independently of the machine itself; and to the second, those that demonstrate the evolution of the machine in itself.

CLASSES OF REQUIREMENTS

The discovery of high-speed tools brought forth the necessity of designing new gear combinations for driving the machine that would permit of a greater power input. This is a requirement of the first class. But it was observation and suggestion that has developed the modern type of quick-change gearing; and this is an example of requirements of the second class.

We aim to be ready to meet these necessities as they arise, and are prepared with systematized knowledge to solve the new problems created; but the improvements or requirements brought about through our observation and suggestion are proportional to the amount of study that we are willing to invest during the course of our daily work.

Our standards for improvements are based on the general principle of simplification of manual operations consistent with the quality of the finished product and cost of production.

Our aim is, in fact, not only to make manual operations easier, but to eliminate manual operations as much as possible. The reason is that we can perfect a machine. We can time a machine and standardize its product much better than we can the operator. And we are now satisfied by daily evidence that, at least in a mechanical sense, machines can do what men can do.

We have in modern machine tools automatic stops, power quick traverse, belt shifters, tool lifters, sizing grinders, and other numerous attachments with which we are familiar. These attachments add in each case some parts, and in some cases complicated mechanisms, to the original machine, in order to increase its output by simplifying the manual operations. The increase and dependability of the output justify the additional expense.

Each of the examples here given is of the same nature, inasmuch as its object has been to eliminate the frequent repetition of some manual operation. They all require the setting of some additional gage to reproduce a given performance, and we may well associate the above with the general study of jigs and fixtures, as their development has been hand in hand.

These accessories do not affect the standard construction or the fundamental lines of the machine to which they are applied. Changes that affect the fundamental construction are of such blended character that it is difficult to point out the different steps of the transformation. The total advance may be appreciated by comparing the modern machine with its equivalent of twenty-five years ago, and the most influential details in this advance can be attributed to the perfecting of gear wheels and their combinations.

In those days it was not permissible to feed a tool with rack-and-pinion motion nor to drive a cutter with an all-gear combination; the tooth marks were clearly visible. And it was not all the fault of workmanship, as imperfect applications of gear trains were many times the cause of such poor results.

We can say, in general, that positive transmission of motion and quick-change-gear combinations are the prominent details that characterize the modern machine tool. These gear changes are quick and simple, with very few exceptions, but there are exceptions, and besides, these are, at their best, manual operations, two good reasons for attracting our attention.

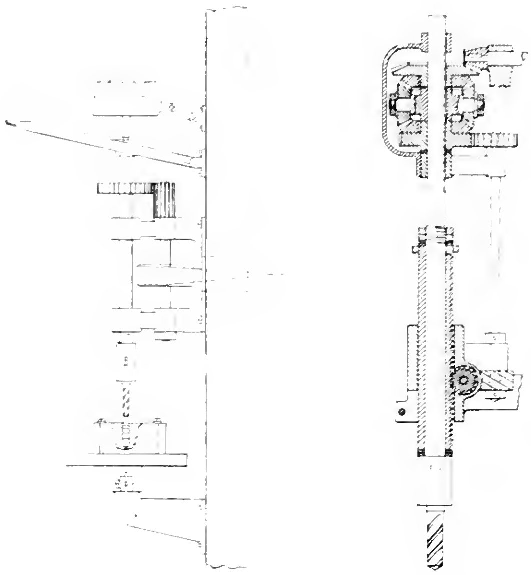

Fig. 1 Fig. 3

Fig. 1 Upright Drill for Testing Hardness
Fig. 3 Drill With Driving Force and Feeding Force Complementary

We may consequently say that the further perfecting of gear trains and their combinations, consistent with our continuous effort for saving manual labor, will bring about the modification of some of those gear changes that are now left to the will of the operator.

PROBLEM OF THE DRILLING MACHINE

As an illustration I will call your attention to one particular application, and I will select the drilling machine. Here

[1] Member Engineers' Club of Cincinnati.

Presented at a meeting of the Cincinnati Section of The American Society of Mechanical Engineers, March 16, 1916.

the changing of tools is ordinarily very frequent. The diameter of the tool is charted with its corresponding speed in revolutions per minute. A quick change of the position of one or two levers and the proper speed is given to the tool.

But to feed this tool properly is a consideration not quite so simple. In the first place, excessive speed will not break the tool, while excessive feed will break the tool. In the second place, if excessive speed burns out the tool, the feed again will break the tool or the machine. The feed is, in both cases, the more important change of the two.

On the other hand, a drilling machine, on account of its constructive capacity, admits of two or three times as many speeds as it does feeds, for the reason that all the feed-change gears must be comprised in the head of the machine. The result is that the same feed is charted for a considerable number of tool diameters.

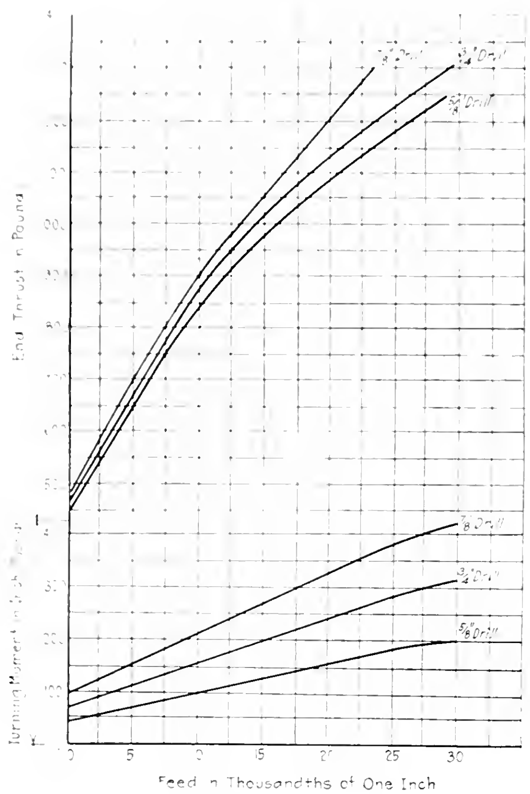

FIG. 2 RELATION OF END THRUST TO DRIVING FORCE

Another consideration is that the amount of feed given on the chart will feed the tool properly after the cut has been started and brought to full diameter without abnormal effort that would indicate that the tool is dull, and for this reason the operator will start feeding by hand previous to connecting with power feed, making certain that the tool is cutting freely, and also will finish feeding by hand in many instances to prevent a breakage as the tool comes through the metal. When using tools in connection with jigs, where said tools carry stop collars to gage depths, it is also necessary to feed by hand against such stops. Consequently, the operator, after making the necessary feed changes, will feed by hand the greater part of the time in many instances.

The conclusion is that the power feed in such a machine does not meet all of the requirements, being more a hand than a power-operated mechanism.

These limitations of the feed gearing are not characteristic of the drilling machines alone, for other machine tools will be found wanting in similar respects if carefully examined.

Now, if we are to continue perfecting gear transmissions, this most likely will be the nature of the requirements that we will have to meet in the near future.

That it is possible to accomplish the desired results there is no doubt in our minds. Nevertheless, as an example, I will suggest an analysis and a possible solution of a plain train of positive gearing to feed the tool in drilling machines that might be considered a step in the right direction in the development of feed gearing.

ANALYSIS OF DRILL-FEEDING PROBLEM

Fig. 1 represents the elements of an upright drill as it is used for testing the hardness of materials. The spindle is driven in a normal way. Provision is made for the application of a given weight to the spindle of the machine. Here, for a given weight and a given speed, the materials under test for hardness are graded by measuring the penetration of the tool in a given time. Tests of this kind have been published in the *American Machinist,* and are quoted here only to substantiate the fact that the tool can properly be fed by a constant pressure. The feeding of drills is at present accomplished by positive motion.

Fig. 2 gives in condensed form the results of numerous tests for determining the values of the end pressure needed to feed the tool,[1] and the torque required to drive the same tool.[2] The values of three tool diameters are given: 5/8 in., 3/4 in. and 7/8 in. There are two curves given for each side, one for the value of the end pressure or thrust, and one for the value of the turning moment or torque. The upper curves, for end pressure, read pounds on the vertical scale corresponding to feeds on the horizontal scale in thousandths of an inch. The lower curves, for the turning moment, read pounds at one inch radius on the vertical scale corresponding to feed in thousandths of an inch on the lower scale. For example, the end thrust required to feed a 5/8-in drill with an 0.011-in. feed is 875 lb., and the torque required to drive it is 100 in.-lb.

The driving force and the feeding force are so related in the actual action of cutting that the one cannot exist without the other; in other words, they are two component forces, and their values are functions of each other. These values, as given in Fig. 2, vary in the same direction, but not proportionally, as may be seen by the relative obliquity of each two curves for the same diameter of tool. It will be seen that as the feed increases the end pressure increases more rapidly than the turning moment.

Fig. 3 shows an elementary construction of a drilling machine where the driving force and the feeding force are complements of each other. This is a differential gearing such as is used on the rear axle of an automobile, and whose construction and efficiency are well known.

PROPOSED DIFFERENTIAL GEAR FEED, IN WHICH THE ADVANCE IS GOVERNED BY THE DRIVING TORQUE

A small bevel pinion is our source of power, this driving a double bevel gear running loose on the spindle. Meshing with the lower half of the double bevel gear are two bevel pinions running loose on trunnions that project from a sleeve; this sleeve driving the spindle by means of a sliding key. These bevel pinions are called planet pinions, and meshing with

[1] Thrust of Twist Drills, H. Hess, Am. Mach., 1907, p. 598.
[2] Power Required to Drive Twist Drills, Frary and Adams, Am. Mach., 1907, p. 210.

them is another bevel gear, called the supporting gear, around which the planet pinions will roll when driven by the first driving gear. The supporting gear also runs loose on the spindle, together with a spur gear, which is the first member of the feed train of gearing. A vertical shaft, two spiral gears, and a rack and pinion complete the feeding mechanism.

The said supporting gear is positively geared to the spindle for feeding. Its motion is proportional to the feeding movement of the tool, and if the tool does not advance this gear will not turn. The said driving sleeve is carried around by planet pinions at one-half the speed of the first driving gear as long as the supporting gear does not turn, but as the speed of the supporting gear, when the tool is feeding, is very low, it only affects the spindle speed on a very small percentage.

The planet pinions exert a tooth pressure on the supporting gear equal to one-half the pressure effective on their trunnions, measured on a radius equal to the pitch radius of the supporting gear. This pressure is transmitted through the feed train of gearing down to the end of the tool. The amount of tooth pressure on the supporting gear and the amount of end pressure on the tool, or, the ratio of these two pressures, depend on the gear ratio of the feed train of gears. The pitch radius of the supporting gear multiplied by its tooth pressure equals the turning moment given in Fig. 2. The tooth pressure of the supporting gear multiplied by the feed-gear ratio equals the end pressure given in Fig. 2.

This mechanism, fitted with the proper feed-gear ratio, will, in driving the spindle with a given torque, produce the necessary end pressure to feed the tool just enough to maintain the said torque. These two forces, the driving force and the feeding force, are functions of each other, and it is necessary that they come to be in equilibrium at the desired rate of feed in order to maintain the feed constant.

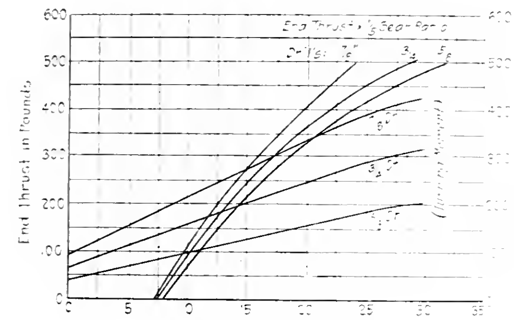

Fig. 4 Relation of End Thrust to Feed-Driving Force. End Thrust Reduced by Gear Ratio of 5:1

Fig. 4 is a modification of Fig. 2. The turning moments are the same as before, but by introducing a feed-gear ratio of about 5 to 1, the values corresponding to end thrust are reduced by a factor of 5. The curve for end thrust in this diagram represents the force inside the differential gear which, multiplied by the feed-gear ratio, will produce a force five times greater to feed the tool. A factor was selected high enough to permit the lines of the end thrust to intersect the lines of the turning moment. As the feed increases the two lines that correspond to the given diameter advance until they intersect. The point of intersection represents the amount of feed reached when the two forces come to be in equilibrium.

With the gear ratio assumed in the present example, a $\frac{7}{8}$-in. tool will reach 0.015 in. feed and maintain 0.015 in. feed thereon; a $\frac{3}{4}$-in. tool will reach 0.013 in., and a $\frac{5}{8}$-in. tool will reach 0.011 in. feed.

Fig. 5 represents the head of a radial drill mounted on the arm of the machine. Only the details that pertain to the present subject are shown, and these again in a very elementary form.

The horizontal shaft, inside the arm, through bevel gears, not shown, drives a second horizontal shaft at right angles. This second shaft carries another bevel gear which meshes with the two bevel gears shown near the bottom of the figure. A clutch between these two gears serves to drive the vertical shaft in either direction. From here on the gearing for driving and feeding the spindle is the same as in Fig. 3, except that the supporting gear is placed above the planet pinions and the driving gear below, for convenience only. The reversing clutch will change the direction of rotation of the whole train of driving and feeding gears.

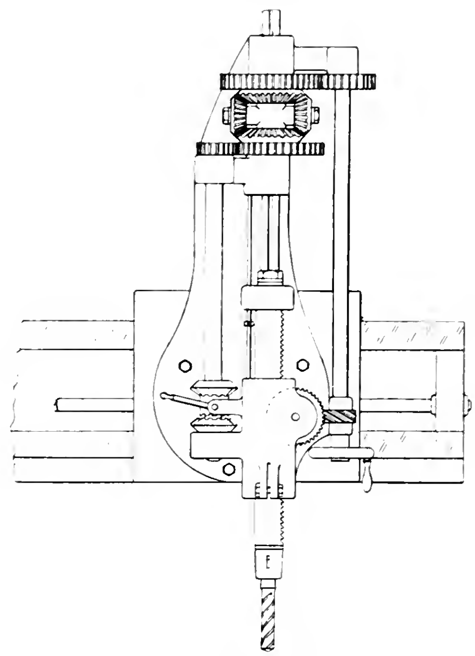

Fig. 5 Drill with Automatic Feed Governed by Driving Torque

The reversing-clutch lever has two positions that correspond to the upward and downward movement of the spindle. It is operated by hand or is tripped by a collar on the spindle, striking an adjustable dog on a vertical rod, shown in a parallel disposition to the spindle. Said vertical rod is arranged to throw the clutch into the reversing position automatically, so that, if the tool is at work and the reversing clutch is tripped, the tool will withdraw from the work, and will do so whether the tool is a drill or a tap. If, on the other hand, the clutch is thrown in, the tool will advance until striking the work.

It will be noticed that the idle movement of the spindle before the tool strikes the work or after reversing, will be a rapid movement. It will also be noticed that the hand wheel shown on the right-hand side is operative at any time and whether the tool is under cut or not, except in the case of a tap, when the reversing clutch must come into action. It will also be noticed that stop collars on drills will be effective when feeding by power. Could this mechanism be realized, the result would be a machine without feed consideration, as far as the operator is concerned.

METALLIC ALLOYS, WITH PARTICULAR REFERENCE TO BRASS AND BRONZE

By WILLIAM M. CORSE,[*] NIAGARA FALLS, N. Y.

LAW defines an alloy as "a coherent metallic mass produced by the intimate mixture, whether by fusion or otherwise, of two or more metals or metallic substances." Our world is composed of about one hundred elements, of which approximately fifty are metals. Of these metals about forty are in everyday use and less than fifteen to any great extent. As an alloy may consist of two or more metals, we can see what a large number of combinations are possible. There are many pairs of metals that have never been alloyed, so the possibilities for research are almost limitless.

Before taking up the better known metallic alloys such as brass and bronze, let us glance at some metals which are now passing from the rare into the common class.

Cobalt is a metal similar to nickel in many respects but has properties which it confers on its alloys that are distinctive.

Chromium is commonly known as an ingredient of some steels and in combination with cobalt forms stellite, an alloy which has quite recently helped out during the shortage of tungsten.

Tungsten is well known now both in high-speed steel and in the tungsten-filament electric lamp.

Calcium is a metal not produced as yet in large quantities, but as a hardener for lead has recently attracted attention. It will harden lead about ten times as much as antimony, which is commonly used for the purpose. The manufacture of shrapnel bullets stimulated this use.

Magnesium is now a commercial product finding its use principally in light alloys.

Vanadium is another metal used in alloy steels and in some bronzes.

Silicon in 1900 was a curiosity but is now produced at Niagara Falls in large quantities.

Titanium is, next to iron, the most abundant metal in the earth's crust. It principal use at present is as ferro-carbon-titanium, which is used as a cleansing agent in steel. It is also used in bronze alloys and its oxide as a white pigment.

Cadmium, thallium, molybdenum, and *boron* can be produced cheaply and are awaiting their extensive practical uses.

Copper, tin, lead, zinc, aluminum, and antimony are the most useful of the non-ferrous group. The metals alone have many uses, but the field is widened when metallic alloys are produced.

Copper and tin with copper above 80 per cent form the true bronzes. Other metals added confer special properties but the dominating feature of the alloy is the copper-tin base. Lead, for example, is added to aid in machining and zinc to promote soundness.

Copper and zinc with copper above 56 per cent form the true brasses. These also are modified by the addition of a third or fourth metal such as tin or lead, but still possess the properties of the basic copper-zinc combination in the particular proportion specified.

For some reason the term bronze is also applied to other combinations than copper-tin alloys; for example, manganese bronze. This is a copper-zinc alloy approximately 60 per cent copper and 40 per cent zinc, to which a hardener, consisting principally of iron, is added. Aluminum bronze is another example; it is an alloy approximating 90 to 95 per cent copper and 5 to 10 per cent aluminum.

Alloys consisting principally of tin or lead to which other metals such as antimony and copper have been added as hardeners, are known as babbitt metals.

Alloys have been known for hundreds of years but their scientific study has been undertaken only during the past twenty-five years. This period has been marked by several distinct phases of development:

1 The advent of the chemist and metallographist into the trade
2 The exchange of information through trade journals and scientific societies. The oldest trade journal was started in 1902 and the two scientific societies, viz., The American Institute of Metals and The Institute of Metals of Great Britain, were founded in 1907 and 1909, respectively
3 The application of knowledge gained to engineering problems and shop methods both from a manufacturing and consuming viewpoint.

These three phases enabled information pertaining to the industry to be widely disseminated, and the exchange of knowledge has led to many permanent advances and made possible many developments; for instance, aluminum is now a commercial article; magnesium, tungsten, titanium, and vanadium are well known and have important uses. The methods employed in studying alloys have been conveniently classified by Roberts-Austen and Stansfield[1] under

1 The chemical grouping of the metals in a solid alloy
2 The separation of the constituents during solidification.

The first of these includes the methods of investigating their specific gravity, electrical resistance, diffusion, electrolytic conduction, thermo-electric power, heat of combination, electromotive force of solution, also the isolation of constituents by chemical methods, and microscopic examination.

The second group deals with those methods involving a study of the separation of the constituents of an alloy on solidification, and includes measurement of fall of temperature during solidification by means of a pyrometer, mechanical separation of the constituents of an alloy by heating to definite temperatures and draining off or pressing out the liquid portion, and investigation of the changes in the magnetic character of certain alloys during heating and cooling.

The methods thus outlined have given valuable results, but according to Gulliver[2] the most fruitful results have been obtained by considering alloys as solutions of metals in each other and studying them by means of the thermometer or pyrometer, and the microscope. The record of temperature gives the melting point, freezing point, and critical temperatures of the alloy; the microscope shows its structures; and these two determinations taken in conjunction reveal very valuable data.

The microscopical study of metals and alloys is known as metallography. In this connection it may be mentioned that

the reports of the Alloys Research Committee to the Institute of Mechanical Engineers of Great Britain are splendid examples of this kind of work and stand as enduring monuments to their authors.

The tensile strength, yield point, elongation, and reduction of area are determined on a machine of the Olsen or Riehlé type, and the hardness determined wherever possible by the Brinell method. The latter consists of forcing a 10 mm. steel ball into the surface of the metal under constant pressure and measuring the diameter of the depression. By referring to a table the corresponding hardness number is found. The scleroscope is also used, but the results are not as dependable as those found by the Brinell method.

Fatigue testing machines such as the White Souther give valuable results in special cases. For example, the resistance to fatigue or vibration of titanium aluminum bronze was found to be about ten times that of manganese bronze, both bronzes being of equal strength. Machines to determine wear have been devised but not as yet widely adopted. A good machine of this kind would be very valuable.

One of the questions frequently asked in engineering circles is, how the ancients tempered copper. Various attempts have been made from time to time to claim the discovery of this lost art but without much success. The facts are that the tempered copper of the ancients was an alloy and not a pure metal. The chemist has shown us that it contained iron and tin in sufficient quantities to harden the metal. The main difference between ancient and modern metallurgy lies in the purity of the metals produced. The ancients really made alloys instead of pure metals, and secured the corresponding properties of alloys while assuming that what they handled was pure metal. While this fact has been known for a long time, the slow dissemination of metallurgical information gives ample opportunity for the country drug store to produce several discoveries of this lost art annually.

While it is generally known that small amounts of certain elements such as carbon, phosphorus, and sulphur exert a profound influence on the properties of steel, it is not as generally known that small amounts of certain elements such as oxygen, sulphur, vanadium, titanium, and phosphorus also exert profound influence on the properties of certain non-ferrous alloys.

The study of the metals in the bronze foundry is a larger proportion of the scientific work to be done than the same study in the iron or steel foundry. The iron foundry has but a few grades of metal to make, while the brass foundry or casting shop may have a hundred standard formulæ for alloys and several times as many for special cases. Each alloy requires the thought and attention of the man in charge. The importance of the study of metallic alloys, I am quite sure, will furnish sufficient work for years to come.

I should also like to mention the need of coöperation between the metallurgist and the engineer. Instances of lack of knowledge on alloys come up every day. For example, a large railway recently specified an alloy of copper 58 per cent, tin 40 per cent, zinc 2 per cent. We inquired the need for such an alloy and received the reply that the service of the part in question demanded a hard metal, and in an effort to find one a consulting engineer was asked to suggest a formula. The suggested alloy is certainly hard, but it is so brittle that if the casting were allowed to drop on the floor it would break into a hundred pieces. Twenty per cent tin in that alloy would have been about the limit.

Another point to be emphasized is the difference which exists between results of test bars and the properties of the casting itself. Design, relation of thick and thin sections, and weight all have a very direct bearing on the result. Many engineers do not possess data on the relation between the strength of the test bar and the strength of the casting. Although the matter has been the subject of a few articles, it will bear repeating, as many misunderstandings arise through a lack of knowledge of this relation. I know there is a wide discrepancy between the two, but do not have sufficient information as yet to warrant the formulation of a rule. I want to mention the fact so that engineers will recognize that the condition exists, and they will be willing to coöperate in getting more data on the subject.

The illustrations are given to bring out the need of coöperative advice and show the sort of problems that arise. These can only be solved by the application of scientific methods and the appreciation by both manufacturer and consumer of the necessity for coöperative work and study. That the field of alloys research is of interest is not questioned by those who have worked in it, and it will only be necessary to present the matter in the proper light to convince engineers of its practical value.[1]

ILLUSTRATIONS

Fig. 1 shows the structure of pure cast copper of high electrical conductivity magnified 100 diameters. Parts of large uniform crystals are shown, the different crystals being of different shade because this metal has been etched with ammonia and peroxide, which attack some crystals more than others, depending on the way the polished section happened to cut the various crystallographic axes. This structure is typical of all pure metals; the only impurities seen here are the few small black spots, which are probably traces of oxide.

Fig. 2. shows this same material at the same magnification after forging. The crystals are very much smaller, and many of them show more or less parallel bands, evidence of the phenomenon known as *twinning*. Although this is a view of forged pure copper, the structure is perfectly typical of all hot-worked pure metals or solid solutions, such as rolled brass, for instance.

Fig. 3. at the same magnification shows the structure of copper cast carelessly, without deoxidation. Melted copper dissolves oxygen from the air very readily in quite large amounts, but when this oxidized copper solidifies on cooling, the cuprous oxide is thrown out of solution, forming a mixture with the metal called an eutectic. This eutectic is shown clearly in this figure as a dark substance filling the spaces between the rounded grains of copper. It is a weak, brittle substance, and spoils the ductility of the metal. The copper crystals are shown here of different shade as in the previous figures, on account of the action of the etching reagent, as explained before, but in both the light-etching and dark-etching copper crystals the oxide eutectic is etched darker than the copper.

Fig. 4. in which the structure is magnified 20 diameters, shows copper containing lead instead of oxygen, and this metal was not etched, so that the copper crystals are not shown. Lead is so much softer than copper that it wears away to a lower level in polishing and does not take as good a polish as copper, so that it always looks dark in a polished section through the microscope. The dark spots here are lead and the bright background is copper. Metal like this is used for soft bearings that must give good service at very high speeds, and not become hot even if lubrication is not always effective. Since copper and lead do not dissolve in each other even when melted, it is hard to cast a uniform mixture of the two, and it takes care and skill to avoid the occurrence of large globules of lead, one of which is shown in part in this figure, and which might so weaken the casting as to cause it to break. An interesting feature of this figure is the presence of very small star-shaped crystals of copper, somewhat like snow crystals, in the large globule.

Fig. 5 is a view of a leaded bronze, or an alloy of copper, tin and lead. This metal has been etched, and the structure is shown

[1] I wish to thank Mr. George F. Comstock for his able coöperation and for the photomicrographs which accompany this paper.

magnified 200 diameters or ten times as much as in Fig. 4. Here two other features are shown on account of the presence of tin in the alloy. The rough-looking black spots with bright centers are not lead, but the soft cores of the bronze crystals, which, being lower in tin than the rest of the metal, were eaten away by the etching reagent, while the parts higher in tin were left bright. The soft cores, low in tin, are found in all cast bronzes, because when bronze first solidifies in cooling from the melted condition the first metal to freeze is nearly pure copper, the tin remaining as long as possible in the liquid part. When cooled so far that the last bit of the alloy must freeze, there is so much tin left in the metal that remained liquid longest that a new constituent, high in tin, is formed. This constituent is shown in this figure as bright irregularly spotted areas, sharply outlined. These areas are bluish gray in color, contrasting quite strongly with the yellow color of the other bright parts of the alloy. The gray constituent is known as the copper-tin eutectoid and is hard and brittle. The lead in this alloy appears as dark gray rounded spots. It makes the metal more easy to machine and gives better bearing properties.

Fig. 6 shows at a magnification of 400 diameters a bronze containing 10 per cent tin and 2 per cent zinc, with little lead. The eutectoid is clearly seen here, and the cores are very distinct. The parts that seem to be at a lower level are the soft, low-tin parts of the crystals which were attacked by the etching reagent and dissolved away from the originally smooth polished surface. The parts standing up in relief are higher in tin and resisted the attack of the etching solution.

Fig. 7, also magnified 400 diameters, shows an alloy of the same general composition as the last one, but of poor quality. There is hardly any eutectoid shown here but instead there are numerous black lines and spots. These are films of tin oxide, which destroy the strength and ductility of the alloy. They show that the metal was not completely deoxidized when cast: in good bronze these films should not be found.

Fig. 8 shows the appearance of a polished and etched section of a soft bearing bronze, with only about 6½ per cent tin, and a little lead and zinc magnified only 20 diameters. Here the only thing shown is the arrangement of the soft cores of the crystals, and this dendritic or pine-tree structure is typical of nearly all cast bronzes.

Fig. 9 shows the alloy of Fig. 8 magnified 200 diameters. The harder bright portions stand out clearly above the softer cores, and contain a few traces of the eutectoid and a few spots of lead. The good bearing qualities of this metal are probably due in large measure to the irregular alternation of hard and soft streaks on any given surface. On a bearing the hard streaks would carry the load, and the soft streaks in wearing away would form microscopic channels facilitating the distribution of oil.

Fig. 10 shows the same alloy, magnified the same amount as in Fig. 9, but in this case the sample was chilled quickly in casting instead of being cast in sand and slowly cooled. The finer grain caused by chilling is apparent, and also the soft cores are more extensive, at the expense of the hard bright portions, but otherwise the structure is the same.

Fig. 11 is an extremely coarse-grained gear bronze, of English manufacture, with about 10 per cent tin and a little lead and zinc. This section is magnified 200 diameters like the last two, and also etched in the same way. The soft cores appear as large black streaks, and the spotted structure of the eutectoid is clearly seen. This bronze would be hard to machine, on account of the learge spots of hard material in it, which would dull the point of the tool.

Fig. 12 shows a similar bronze with 11 per cent of tin, etched in the same way and magnified 20 diameters, but cast in a chill. The very fine grain as shown here can be easily and certainly produced by chilling this alloy, and is far superior to a coarse structure from all points of view.

Fig. 13 shows a sample cut from the chilled face of a bronze gear containing 11 per cent of tin, magnified 200 diameters, or ten times as much as Fig. 12, and etched differently, so that all the surface is darkened except the hard high-tin eutectoid. The soft cores of the crystals are shown here as black streaks with bright centers, but the main part of the alloy was darkened by ferric chloride to give a greater contrast between it and the bright eutectoid. The interesting point about this structure is the very small amount of eutectoid present in spite of the high tin content, and the result is that this metal is easy to machine and still hard enough to make a good gear. Such a structure is produced merely by chilling the metal as soon as it is cast.

Fig. 14 shows the same metal, etched and magnified in the same way, but slowly cooled in casting. The large amount of eutectoid here makes the metal brittle and hard to machine. The soft cores in this alloy are so coarse that their centers form rather large light areas, but the eutectoid is much brighter and of more irregular shape.

Fig. 15 shows the structure of a harder gear bronze, with 13 per cent tin and 2 per cent zinc, sand-cast, and etched and magnified 200 diameters. There is still more eutectoid here, and its spotted structure is clearly brought out. Bell metal has only a little more eutectoid than this.

Fig. 16 shows the structure of a rather coase-grained and soft manganese bronze, magnified 20 diameters. The metal when just solid in cooling from the liquid state consisted entirely of the dark constituent; on further cooling the bright needles separated out along the cleavage planes of the original crystals. The different original crystals may thus be distinguished, not only by the color assumed in etching, but also by the directions of the bright needles in them.

Fig. 17 shows a fine-grained, harder and stronger manganese bronze, etched and magnified in the same way. This metal was cooled faster in casting, and the bright needles did not have much chance to develop before the temperature dropped too low for any further growth.

Fig. 18. Another non-ferrous alloy which has strength and ductility comparable with manganese bronze and steel is aluminum bronze, a name applied to alloys of copper with up to 10 or 12 per cent aluminum. The structure of a typical 10 per cent aluminum bronze, cast in sand, and magnified and etched in the same way as the previous views of manganese bronze is shown here. This alloy is seen to be normally coarser grained than manganese bronze, and to have more of the light constituent, which is softer, and less of the dark constituent, which is harder. Consequently its yield point is lower than that of manganese bronze, but its ultimate strength and ductility are just as good, and in endurance or resistance to fatigue, and in bearing qualities, it is far superior. It also resists corrosion very well.

Fig. 19. We have found that the addition of iron to aluminum bronze refines the grain very decidedly, and gives a higher yield point and slight improvements in other properties except the resistance to corrosion. Here is shown the typical structure of an alloy of copper with 10 per cent aluminum and 4 per cent iron, magnified and etched as in Fig. 18, the distinctive characteristics being the fine grain and absence of the long parallel needles always seen in ordinary aluminum-bronze castings.

Fig. 20 shows the structure of a good sand-cast sample of 10 per cent aluminum bronze etched as before but magnified 400 diameters. The dark constituent is here seen to be of duplex composition, containing light and dark particles. This in fact is a eutectoid similar to the one seen in the tin bronzes, but it etches dark instead of light.

Fig. 21. Aluminum bronze shares with steel the property of hardening in quenching, with the formation of a peculiar martensitic structure, as shown here. This structure was produced by heating a small piece of 10 per cent aluminum bronze to 900 deg. cent. and quenching it rapidly from this temperature in cold water. This is magnified 200 diameters. Such metal as this is strong, often taking over 100,000 lb. per sq. in. to break it, but has no ductility. It has a hardness of about 200 Brinell. As in the case of steel, a double heat-treatment consisting of quenching followed by tempering gives superior qualities.

Fig. 22 shows a structure obtained by reheating a quenched 10 per cent aluminum bronze to a dull red heat and cooling slowly. The structure is shown magnified 200 diameters and is much finer than is ever obtained in an untreated casting. This metal has a high yield point and a high ultimate strength, with over 10 per cent elongation and very great resistance to fatigue.

Fig. 23. The casting of aluminum bronze is especially difficult because of the easy formation of oxide of aluminum in the metal and the great difficulty of removing it afterward. This figure shows some inclusions of aluminum in aluminum bronze, magnified 200 diameters and not etched. It takes special care and the use of special fluxes to prevent the occurrence of such inclusions in all alloys containing notable quantities of aluminum.

Fig. 24 shows the typical structure of the light alloys, composed largely of aluminum, magnified 50 diameters. This particular alloy contained 8 per cent of copper, and its polished surface was etched to darken the copper-aluminum eutectic, leaving the nearly pure aluminum crystals bright. The eutectic is very brittle, but much harder than aluminum, so that although this alloy has hardly any ductility, it is harder and stiffer and a little stronger than the purer metal would be.

GRAPHICAL CONTROL ON THE EXCEPTION PRINCIPLE FOR EXECUTIVES

By FRANK B. GILBRETH, PROVIDENCE, R. I.

Member of the Society

We have stated many times that the greatest waste in the world today is from unnecessary, inefficient and ill-directed motions. Many people think that this statement refers only to such activities as those of the bricklayer, the shopworker and other kinds of mechanics and manual workers. It does refer to them, but by no means to them only. It refers to the activity of every one and, by no means least, to that of managers and all other executives.

To one trained in the sciences of management and motion study, nothing is more ridiculous and pitiful than the average executive when he tries to enforce new motion methods on those farthest below him in the industrial scale, while he at the same time commits nearly all the motion wastes in his own personal work. The personal work of the executive should consist as much as possible of making decisions and as little as possible of making motions. General recognition of this fact has resulted in the common practice of assigning to the executive one or more secretaries, or clerks, to relieve him of certain parts of his work which involve mere motions and less important decisions than that part of the work retained by the executive.

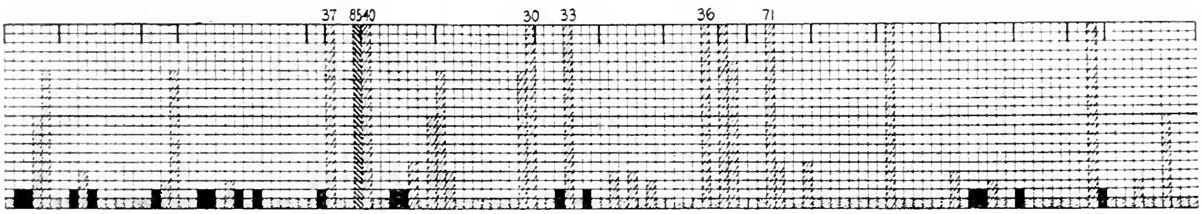

Fig. 1 Simple Illustration of a Chart Used on the Exception Principle

Such a chart may, for example, show the promptness of performance of an information bureau of a factory in charge, say, of trade publications, estimates of work under consideration, and records of design sketches. Each horizontal space may represent a specific request for information and each vertical space the time required to supply it. Colors may be used to indicate notable time differences. The point of the exception principle is that the chart shows at a glance when it took too long for a definite inquiry. Then it may be the duty of one individual to ascertain why, for instance, as long as 10 min. was necessary and another when the time is, say, over 20 min. In the so-called three-position plan of management (in which the occupant of any particular job gets supervision from the one promoted from it and serves as a tutor to one in line to fill it), the result is an effort to keep the time intervals within the safety zone, so to speak, so that No. 1 of the three-position plan is not likely to be demoted to improve the service.

INFORMATION A SATISFACTORY CHART SYSTEM SHOULD AFFORD

Some executives are furnished with charts which show by means of comparable curves the increase or diminution in outputs, costs, overhead expenses and, in comparatively rare instances, even in results as compared with budgets. As compared with an organization which has no cost system, such a recapitulation even in the form of an "expenditure system" and such cost statements and graphical charts are a great step forward. No cost system nor chart system, however, can be considered really satisfactory unless it fulfills the following requirements; i.e., it must determine and show —

1 What the quantities of individual outputs should be (prophecies of outputs)
2 Prompt records of individual outputs
3 What the costs should be (prophecies of costs)
4 Prompt records of costs
5 Causes of fluctuations and deviations of outputs and costs from prophesied outputs and costs.

The executive may have much to do with originally determining items 1 and 3; but after the computations of 1 and 3 have been completed, he can best attack the problem of enforcing items 2 and 4 and, also, of determining 5 by the use of graphical charts. He should be provided with charts which will tell him how promptly such records of output and cost have been made; or, in other words, how much time has elapsed between the completion of the output and the recording of it and its attending costs.

A long experience has shown us that the by-products of a properly operated chart system are even more valuable than its direct product. We find that the psychological effect of the variable "promptness" itself makes the curves representing outputs and costs fall more nearly in the proximity of the established norms and locations prophesied on the charts. Such charts give the executive and his colleagues accurate measured information of deviations from class in all departments. The motions that an executive would expend in getting information by such old methods as, for example, walking through the works to see with his unreliable eyes conditions which are not typical, partly owing to his presence, bring results of little value compared with the results that can be obtained by the same amount of time and motions concentrated on those facts and conditions which cause the great fluctuations from the desired output.

Presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, December 1916.

It is obvious that the foreman, or other functionary, should see promptly all the records of output in his particular department after they are achieved. In most cases he will be able to handle his duties still more satisfactorily if he, also, sees the costs of the output of his department. The time of the over-foreman, however, who may have several foremen and departments under him, is too valuable to have him, also, examine with care all the records of all the men under him. Consequently, he should be furnished with information in concise form, in order that as little as possible of his time may be taken. This has often been furnished him in the form of "averages."

USE AND VALUE OF PROGRESSIVE AVERAGES

Ordinary averages have their use. Progressive averages are, however, more valuable, because they show the trend of progress and of efficiency. It sometimes pays to make ordinary averages, but the value of examining such ordinary averages is slight compared with the benefits which result from concentrating the same amount of motions and attention on those individual cases that brought the average away from the ideal. A case of "bad average" may be the excuse for "putting the foreman on the carpet," but the results of this do not compare with the good results that are derived from having the over-foreman investigate promptly the case or cases that spoiled the average.

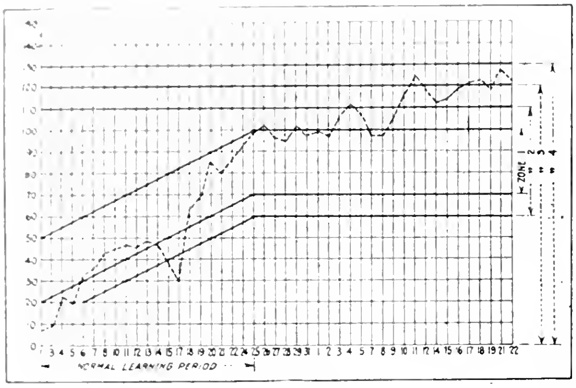

Fig. 2 Example of Exception Principle Chart Covering Output of an Individual, Including Learning Period

In this chart zones are established so that points of performance falling below or above certain limits come automatically by that fact to the attention of certain individuals. The lower the record or the higher the record the higher in the industrial-management scale will be the individual who must inquire into the conditions. The results may indicate poor instruction or incompetency in foremanship or they may bring the executive into personal contact with the worker in the matter of commendation for unusually high performance.

Moreover, the decisions of the over-foreman can be made more quickly, for he has the information which comes from locating the trouble accurately. Instead of "tearing out" the foreman or the workmen, he will find, from the causes marked on the chart, that the worker's low output is due to lack of the proper tools; to his not having been furnished with tools in standard conditions; to the routing system having failed to give him proper materials in the right quantities, in the right sequence, at the right time; to something which has gone wrong with the equipment or surrounding conditions; to the man's not having been properly instructed; to there having been an unwise selection of the man or the machine, or both, for the particular job.

The worker, also, is more careful not to do anything which is not expected of him, because he knows that the exception will surely be noticed by the executives higher up and will interfere with his chances for promotion or transfer to work of a more desirable kind. Knowing that they will be investigated properly will create a tendency on the part of the foreman and the workers to coöperate with others whose work affects theirs, or who in turn may be investigated. This coöperation becomes general, and sooner or later becomes a habit.

OPERATION OF THE EXCEPTION PRINCIPLE

Now the time of the executive next above the over-foreman is still more valuable than that of the over-foreman, and so on up to and including the managing director or president. No executive should make a routine motion of handling, turning over or examining charts containing data, either normal or with considerable deviation from class, where the causes of the deviation can be handled properly by those in lower executive positions. The exclusion of such cases can be obtained by having the executives determine *zones* on the charts, it being understood that as long as the points fall within the zone he is not to see the charts unless he specially requests to see them. He is, however, to have sent to him, for initialing, any chart having a point that falls outside his excluded zone.

An executive of any class will find it beneficial to see exceptionally large cases of deviation on the desired side of the line so that he can recognize and appreciate and take a personal interest in cases of unusual efficiency. It is through such cases that he gets in touch with unusually good methods. This is a check on the exception principle of the time-study-man's work. It also gives the executive valuable opportunities on the exception principle for proper managerial decisions in cases of the selection of candidates for promotion under the "three-position plan" of promotion and organization building. The curves showing progressive averages of departments may be examined at times farther and farther apart, these intervals to be determined in each particular case by the favorable or unfavorable comparison of records of such averages showing outputs and costs, with the prophesied outputs and costs. The executive is thus relieved later of work which is necessary at first, but which is not necessary when the particular case is running satisfactorily.

It is impossible to prophesy with accuracy what the amounts of outputs and costs should be without motion study and time study. But once these have been made and the actual outputs and actual costs approximate those prophesied, the high executives should devote very little time indeed to inspecting this class of charts. Instead, they should spend their time on other work, other departments, and more important things where their supervision will bring more valuable results.

It will be seen that these "Output, Cost and Causes Charts," with the "exclusion zones," enable the executive to eliminate the motions required for general oversight and inspection until a place on a chart is brought automatically to his attention where he can actually help those below him and furnish them with better instructions for handling their work more efficiently; or for making such changes as will naturally result in promotion, or the selection or shifting of individuals better fitted to do work elsewhere. The possibilities of relieving the executive of unnecessary motions and of enabling him to be more efficient in his own work are not exceeded in the case of any manual worker.

THE PENCIL ELECTRODE METHOD OF WELDING FOR BOILER JOINTS

By E. A. WILDT, SCRANTON, PA.[1]

THIS paper has special reference to the welding of joints of drums and to boiler shells as the latter term is commonly understood. The trend of the times is towards that type of boiler in which all the tubes are bent, particularly in the large units such as those at the Commonwealth Edison Station in Chicago, the Delray Station in Detroit, the Ford Automobile Factory and the Solvay Process Company. Since the dimensions of the boiler rooms are growing out of all proportion to the size of the engine rooms, and every item making for a decrease in the size of parts so as to reduce the room for the boilers is in demand, much higher pressures will be resorted to—an item for making the reductions required. Drums are to be used up to 60 in. in diameter, and in order to bear a pressure of 300 lb. or 500 lb. the thickness of the plate will be very close to $2\frac{1}{2}$ inches.

With regard to making the joints in such a drum, is it not more feasible to weld them instead of employing the usual butt strap? There are several methods of making this joint by spot welding, and that which seems to have forged its way to the front is the pencil form of electric welding, which is now fairly generally used in steam-boiler work, although as yet recognized only for low pressures. The weld made by this process is not so hard as others of the autogenous kind.

In a weld, two pieces of metal heated to the proper temperature are united into one solid piece. Success of the process depends on bringing the pieces of metal to the proper heat. For this purpose we have the oxy-acetylene torch, the thermit process and the electric arc, the last of which is the form of modern welding particularly referred to here.

Electricity is used only to supply the heat, and in the pencil method only just enough heat is obtained to accomplish the joining of the two metals. No reference is here made to any particular design or set of apparatus: some are built to use a uniform voltage, others to use uniform amperage or uniform wattage. All autogenous welding is accomplished by adding new metal to the joint to be made, and it is only in the pencil electric arc method that positive incorporation of the added metal with the metal to be joined is secured. The opposite was the case in some recent failures in other forms of electric and gaseous welding wherein fluidity of both the added metal and the pieces to be joined is a necessary condition. By the electric pencil method fluidity is avoided and only just enough heat is used to make the plate and the electrode plastic, and there appears also to be an action in it which in the direction of the current tends to pull the metal from the electrode to and into the plate when just at the proper heat. This is so much in evidence that welding can be carried on overhead without the metal dropping upon the operator.

The temperature in the added metal in the gaseous and electric carbon type wherein fluidity is a condition approaches 2800 to 3000 deg. fahr., while in the electric pencil method the temperature in the metal being added is not more than 1500 deg. fahr. As a result the added and the adjacent metal in the weld is not rendered so hard as would otherwise be the result. This is also proved by the fact that, while cutting can be done with other methods, no cutting can be done with the metal electrode.

This point that the temperature of the arc is so high, so hot, that there is danger of the metal becoming vaporized, is answered by the fact that the conditions surrounding this particular form of spot welding are analogous to and the same as for "forge welding" as carried on by the everyday blacksmith at his anvil: there he has a fire very much hotter than the pieces to be welded are required to be heated to; in fact, it must be so: there must be a considerable surplus of heat for quick action; the blacksmith watches and if through carelessness the pieces are overheated, he says they are burned and spoiled and has to begin over again.

No other form of welding has the characteristic this one has, wherein there is an automatic action which prevents overheating, actually showing that in this regard it is equal if not superior to "forge welding."

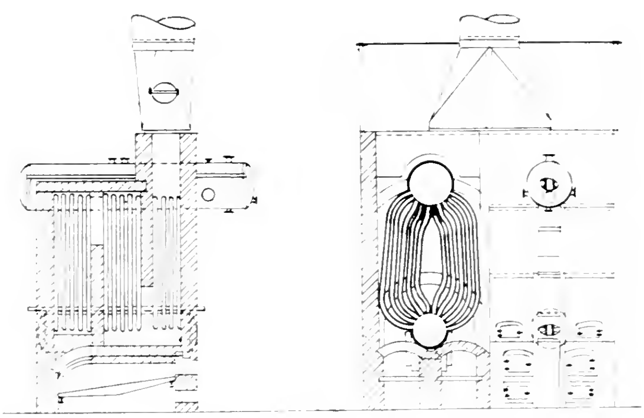

FIG. 1 BATTERY OF TWO 100-HP. WATER-TUBE STEAM BOILERS. THE WELDED HEAD JOINTS ARE VISIBLE OUTSIDE THE BRICK SETTING

The form of welding approved in the A.S.M.E. Boiler Code, known as Forge Welding, entails in its operation the production of big expansion strains, because the whole seam and the seam only is made at a welding temperature, producing an upsetting of the plastic metal by the unexpanded portion of the adjacent metal, so that when the forged welded seam has cooled off, the adjacent unexpanded metal produces tensile strains of very considerable strength, tending to pull the welded portions apart as it contracts, to the extent of close to $\frac{1}{8}$ in. per ft. of the seam. In comparison with this, the metal electrode pencil method is a great improvement, because due to the very small area of metal heated the expansion strains are but fractional and may be considered negligible. Both the approved forged welding and this method of welding which is hereby submitted to the Boiler Code Committee for approval are exactly alike in the particular that the metal is not heated in either beyond the point just necessary to produce welding: when it comes to expansion strains they are less in the latter, and in both methods the weld improves with age.

[1] Lackawanna Boiler and Grate Company.

Abstract of paper presented at the Steam Boiler Session of the Annual Meeting, December 1916, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Although the electric heat reaches an estimated temperature of 6500 to 7000 deg. fahr., in this process the metal wire does not have time to reach this temperature before it is added to the plate or in the usual groove which is to be filled with the welding metal. As fast as the metal wire becomes just plastic, the pencil must be advanced towards the work, or the arc gap will become too long for the electric arc to maintain its circuit. The distance needed for the arc does not amount to much more than 1/16 in., because the voltages used are low, rarely exceeding 60 or 70, and failure on the part of the attendant to maintain this distance by constantly advancing the pencil is met at once by the extinguishing of the arc, because the gap becomes too long for it to maintain itself.

Only in this process, carelessness is practically eliminated, both as to overheating and heating any considerable area, and the heated area is confined to the smallest dimensions

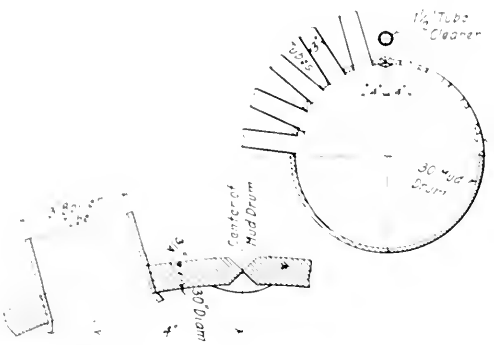

Fig. 2 Cross-Section of Mud Drum, Showing Electric Weld Which is Not in Contact With Fire

of any; therefore the expansion and contraction strains are smallest. The wire forming the electrode only gets red hot at the point, showing the very localized character of the heat, the balance of the wire remaining black; while in the carbon form of electric welding, the carbon gets very hot from the point up to the holder.

Tests have shown that for pressures of 500 lb. per sq. in., and with plates of 2½ in. or similar thicknesses, this method of welding makes a better joint than straps and rivets. The maker of such joints can always know by the hydraulic test whether his work is done perfectly or not. Test after test shows there are no leaks; all you have to do to insure a perfect job is to secure an operator willing to do a good job, pay him well, and it is fair to say that it is then practically impossible to do a defective weld by this method.

In electric carbon arc welding of rolled stock, the metal in the weld cannot have the same properties as that in the original piece; it may have the same tensile strength but it will not have the same elasticity. This is a limitation in *any* welding process, but in this particular process the metal in the weld is changed the least of any, and in fact shows a tendency towards a fibrous condition. The metal of the weld can be controlled by the kind of metal that is added; low carbon steel will make the weld more ductile, high carbon steel will make it higher in tensile strength. A test piece made up entirely of the welding wire showed an elongation of 16 per cent.

In order to be sure that a joint so made will be stronger than the plate, and last indefinitely, it is only necessary to keep on adding new metal until the cross-section on both sides amounts to more than the plate itself. This can be carried to extremes, and may as well be, just filling the groove, usually V-shaped, the extra metal to lap over on each side ⅜ or ½ in., and made in bulged form, both inside and outside of the drum, taking on the form somewhat of a butt strap joint.

There has just recently been put into service, with a view of trying it out in actual practice, a small water tube steam boiler (Figs. 1 and 2) of the vertical 2-drum type, with all the tubes bent tubes, the drums in which have not a rivet in them. Heavy tests have been applied, and there is not the slightest doubt that the men who have to do with the erection of this boiler do not anticipate any danger to anyone from it. Of course, it is realized that the construction has not been approved, but it is necessary for someone to take a stand and bring it to a head. Without something to show and to test, there will be no basis on which to ask for an approval. The situation is somewhat analogous to the man who wants to obtain a job as a stationary engineer,—not having a license he cannot obtain the job and not having the job he cannot obtain the license.

DISCUSSION

John C. McCabe. I would like to ask Mr. Wildt as to the temperature of 1500 deg. fahr., which seems to me rather low. I would like to ask also how he eliminates the possible stresses set up internally in the weld. As I understand the problem, if he has a differential for each degree difference in temperature between the different plates, there is an internal stress of about 195 lb. The other point is, you can determine the safety of a vessel by the electrostatic test. It is well known that electrostatic pressures are seldom allowed anywhere near the elastic limits of the metal, and in the tests and investigations of failures made, I have found the welding material varied, the per cent of elongation running from a fraction of one up to 11, and in view of the bendings or flexures that occurred in the best-formed cylinders, I fail to see how an autogenous vessel, as we understand the problem now, can be considered a safe one.

Christopher H. Bierbaum. Is not the great difficulty with all autogenous welding for boiler plates the fact that so much of the plate adjacent to the weld is heated, the elastic limit of the plate reduced, and its elongation increased? The test pieces which have been exhibited here show that very fact. There is no break in the weld. We know that autogenous welds can be made as strong and stronger than the original metal, and especially in the case where the weld is left a little thicker than the body of the metal itself. But do not the internal strains set up and the heating of the plate adjacent to the weld decrease the elastic limit of the metal in the neighborhood of the weld, and induce conditions which should be very carefully determined before any theoretical conclusion can be drawn?

P. A. E. Armstrong.[1] I do not think the forge process of welding is the only process valuable for boiler work; it is not as reliable as could be desired because of the difficulties of thermal disturbance in the metal in the vicinity of the weld. Thermal disturbance is brought about by two things, time and heat. In the vicinity of the weld the grain of the steel is enlarged and the tensile strength of the metal has fallen about one-third. I have conducted over a thousand tests on welds

[1] North American Company, 30 Broad St., New York.

in Sheffield, England, in working up a high-class steel suitable for welding, and found that with ordinary 0.30 to 0.40 carbon steel it was impossible to get more than about 60 per cent of the original strength, yet the breaks did not occur in the weld but some two or three inches away from the hammered area. In every instance the break occurred because of an enlarged grain.

The crystal grain of the metal, providing the thermal disturbance has not reached the point of incipient fusion, can be recovered by subsequent heat treatment, but this is hardly applicable for boiler work; I think it is absurd to talk of annealing the shell of a boiler 30 ft. in length. When annealed, this shell would expand and buckle in all directions. If this boiler had riveted joints, the expansion and contraction would be so great that a movement would be set up at the riveted joint, and no amount of calking would give a tight joint; in all probability it would augment the looseness of the rivets.

The oxy-acetylene or gas process generally is a very good one, but the thermal disturbance in the metal outside the weld is very similar to that present during forge welding. The electric carbon arc welding is worse. The electric bare wire welding, known as the metallic pencil welding, overcomes thermal disturbance to a greater degree, but the deposited metal in the weld is distinctly cold-short. This cold-shortness could be improved by annealing, but this is quite impossible under boiler conditions. By duplicating steel bath conditions, however, we obtain a fusion process, where the fused metal has a structure which is practically as good as the original steel.

If you take a bare wire electrode and coat it with a large quantity of slag, it is possible to melt this electrode so that the fusion takes place under the slag and the deposited metal would have all the characteristics of ingot steel of a given carbon content. Such an electrode has been developed and is extremely suitable for the welding of boilers and pressure tanks generally. The exterior slag coating of this electrode has the effect of localizing the heat. The metallic core is fused so rapidly that there is practically no thermal disturbance in the vicinity of the weld and complete fusion takes place.

Fig. 3 shows a bare wire electrode. A globule of metal is just leaving the end of the electrode, to be passed across the arc and deposited upon the metal to be welded. The flame or highly incandescent gases immediately underneath the electrode are very nearly neutral; at the outside of the arc flame the burning gases are extremely oxidizing. It is here that the damage takes place. A very interesting experiment can be conducted to prove it. If a bare wire electrode is fused, a crater is formed immediately beneath the fusing end of the electrode. If the circuit is broken and the arc extinguished, then at the bottom of the crater there is a complete absence of oxide of iron, whereas on the top edge of the crater and right over the deposit a layer of about 0.01 in. of oxide of iron is present, which proves that in the center of the metallic arc there is a neutral place. If the flame is examined spectroscopically, its oxidizing nature can be very quickly traced, and the neutral zone can be discerned in the center of the flame when the outside of the arc flame is slightly disturbed.

The slag electrode in operation is shown in Fig. 4. The end of the electrode is in actual contact; in the bare wire case there is a space of about 1/8 in. between the fusing end of the electrode and the work. There is a complete absence of the arc flame effect, and the incandescent slag is passing off from the end of the electrode on to the work. The atmosphere of the slag electrode is practically neutral as the vapor is composed of vaporized slag and not of highly incandescent gases. The voltage across the arc is higher than that of the bare wire system, because the vapor offers a greater resistance to the path of the current, although the arc is shorter and should take only about half the volts to get across, if both arcs were atmospheric.

Fig. 5, 90 magnifications, shows manganese steel of 12 per cent deposited upon manganese steel of a like content. There is no thermal disturbance. The diffusion between the original and the added metal is very complete, showing an entire absence of oxide. The cementite occurring in the globule formation and very evenly distributed over the mass shows absence in the deposited metal of austenic needles.

Fig. 3 Bare Wire Electrode

Fig. 4 Slag Electrode

Fig. 6, 90 magnifications, shows 0.125 carbon deposited upon 0.65 carbon. There is complete diffusion, and the carbon of the original steel is saturating into the lower carbon of the added metal. There is a complete absence of thermal disturbance immediately adjacent to the weld; the grains of pearlite and ferrite are the same size at the area of diffusion as they are half an inch under the weld, the time factor playing a very important part. I have seen a piece of low-carbon steel which has been for about six months at 600 deg. cent., the ferrite grain of which when etched was 1/2 in. across. This metal was absolutely cold-short, had practically no ductility and was extremely low in tensile strength. After submitting to two heat treatments the grain of the metal was practically normalized.

As it is impossible, in a general way, to anneal welds in boiler construction and so normalize the grain, it is essential that the time factor be reduced as much as possible. This illustration proves it. The heat was at least 6000 degrees, the time something less than a second; hence the grains did not have the time to change and assume the size and formation of the superheated temperature. The metal in the vicinity of the weld is quite as strong as it was before welding, and the added metal will have all the characteristics of ingot steel, in this instance 0.125 carbon. The structure of the added metal is given in Fig. 7, 250 magnifications. It is taken about half an inch above the line of diffusion. The grain is of small size and excellent structure, the pearlite and ferrite grains being very consistently arranged, and there is a complete absence of enlarged grains due to subsequent thermal disturbance.

Table 1 is taken from a Report of the Department of Commerce and Labor, Steamboat Inspection Service, dated January 27, 1916, on the tensile strength of four samples of slag welding for marine boilers submitted.

TABLE 1 TENSILE TESTS ON SLAG WELDED PLATES

Numbers on plates	1	2	3	4
Thickness of samples, decimals in.	0.491	0.494	0.743	0.521
Widths of samples, decimals in.	1.00	0.991	1.00	1.023
Strain at which each sample parted	28000	27500	42120	31890
Strain per sq. in. of section, lb.	56689	56530	56680	59840
Reduced thickness of sample	0.685	0.660	0.948	0.852
Reduced width of sample	0.282	0.300	0.725	0.419
Reduction of area, per cent	60%	59%	7%	23%
Length of straight part in center of test piece, in.	8	8	8	8
Elongation, percentage of	29%	25%	7%	14%

Sample No. 1 is the original steel of about 56,000 lb.; it broke at 56,680 lb. Sample No. 2 is a plate cut in half, welded and machine flush; this broke at 56,530 lb., $2\frac{1}{2}$ in. outside the weld, proving that the weld was stronger than the original metal and that there was no thermal disturbance in the vicinity of the weld. The elongation is 25 per cent, but this shows absolutely nothing, because the sample started to neck $2\frac{1}{2}$ in. away from the weld, and the reduced area resulting from this necking caused the fracture. Sample No. 3 is a plate cut in two, welded and reinforced $\frac{1}{4}$ in. down the entire length of one side. This sample broke in the weld and the tensile strength was 56,680 lb., identical with sample No. 1, which proves that the weld was of about 56,680 lb. tensile strength. The elongation was 7 per cent, and as the sample broke in the weld the necking occurred there, and it is quite reasonable to suppose that the elongation in the weld was somewhere near 7 per cent. Sample No. 4 was a plate reinforced on one side and then the welded metal entirely machined off, leaving the original plate at its original thickness. This plate was prepared so as to find out what effect the thermal disturbance had upon the metal adjacent to the weld.

As will be seen, the tensile strength of the metal has been increased and the ductility reduced. This is to be expected from the slight thermal disturbance taking place, as the added metal was as thick as the original steel. The results according to the test sheet show at least the great tensile strength of the welds made by this slag electrode.

Corrosion and welding are closely associated. It has been proved that corrosion is electrolytic in character, the positive pole of the small galvanic couples being highly corroded and the negative pole being practically free. When testing a piece of boiler steel for polarity, it is shown that there are numerous places where corrosion can be set up, due to electrolysis; all mechanical work on iron and steel will immediately start corrosion due to electrolysis, the electrolyte being supplied by the atmospheric moisture. A simple experiment will prove this. If a small portion of a piece of steel, neutral

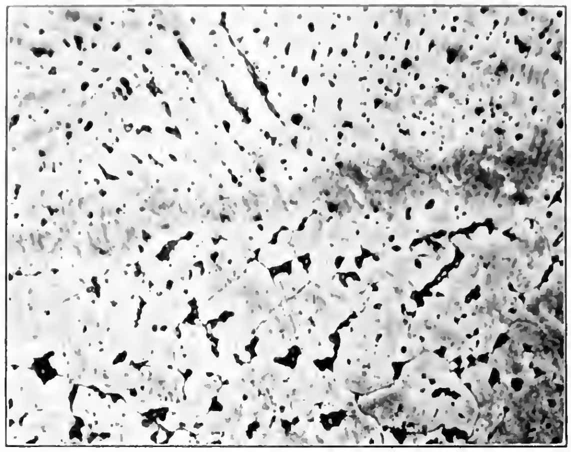

FIG. 5 12 PER CENT MANGANESE STEEL ON 12 PER CENT MANGANESE STEEL, MAGNIFICATION 90

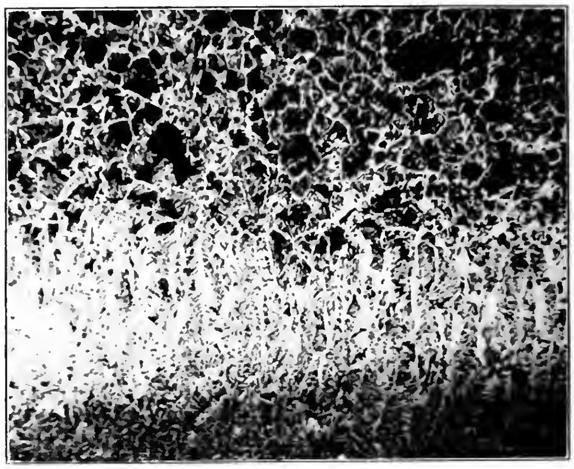

FIG. 6 0.125 CARBON STEEL ON 0.65 CARBON STEEL, MAGNIFICATION 90

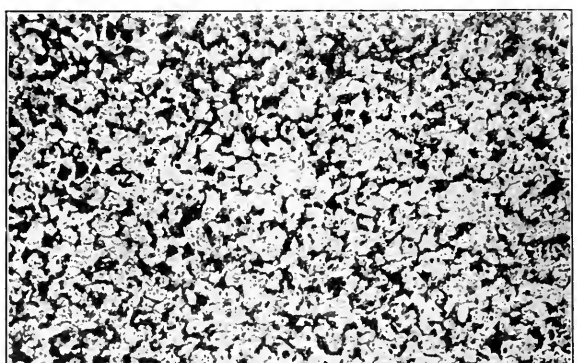

FIG. 7 STRUCTURE OF ADDED METAL, MAGNIFICATION 250

across its entire area, is hammered and tested for polarity, a voltaic circuit is present, the stress from the hammered portion being electro-positive and the original steel being

electro-negative; therefore it follows that every rivet head, calked edge or hammered portion of the boiler is electro-positive to its shell generally. Thermal disturbance and small mechanical work will set up polarity, and such a weld will be distinctly electro-positive to the surrounding metal. This is particularly noticeable in machine welded flue tubes in locomotives; 90 per cent of the corrosion taking place will always be present when the added length of tube has been made to recover short tubes. Autogenous welding is distinctly electro-positive to the surrounding metal, because the added metal is less pure, containing magnetic oxide of iron and other impurities. An oxy-acetylene or gas weld made on a pressure tank or boiler may be badly pitted by corrosion. A weld by carbon arc corrodes to a greater extent, and welds by the bare wire pencil method are certainly no better. Tests can be easily made by means of a millivoltmeter.

The deposit by the slag electrode is so pure that the added metal by this process is quite electro-negative to the surrounding metal and to a very large degree obviates corrosion at the weld. If the subject of corrosion is borne in mind, I am tempted to say that forged welding will not be permitted; some fusion process will be adopted wherein the corrosive influence of an electrolytic circuit is to a very large degree restricted.

Victor Mauck. In all processes of welding it is necessary to raise the temperature of the metal to be welded to the point of fusion. Given a neutral flame free from non-combustible impurities, such as sulphur, nitrogen, etc., the arrest of the heating process at the exact point of fusion, and a uniform contact of the parts, a perfect weld of practically equivalent strength, section for section, to the adjacent metal would result. However, there are so many factors involved over which we have but indifferent control that this result is rarely attained. It is therefore necessary first, to rate the efficiency of the weld based on average manufacturing practice; second, to provide an ample factor of safety. A sufficiently high hydrostatic test pressure should be specified to insure ample minimum strength; and I lay particular stress on high test pressure.

In a riveted joint the fundamental operations are uniform and of a mechanical nature, affected but slightly by the human equation. The weld on the other hand has a much higher theoretical strength, but is *all* human equation, hence the importance of the high test pressure. A weld will vary widely in strength throughout its length, but this variation is less than in a riveted seam. Welds cannot be made commercially (except one form of electric weld) without more crystallization of the metal, and will lead to eventual failure under vibratory action if provision is not made for a sufficient factor of safety. It is possible to surround the processes with all reasonable precautions, in the public interest, and at the same time allow them that latitude for development they deserve, and which is conceded them abroad.

The process of electric welding by induction probably attains the nearest to the theoretical possibilities of any weld we have. The operation, being entirely mechanical, is uniform and under perfect control. There is no crystallization of the metals and the human equation is practically eliminated. The heat in this process is generated within the stock itself, radiating from the surface as opposed to the application of a very intense external heat, as in the oxy-acetylene flame or electric arc. In the latter case the surface is overheated before the body of the metal reaches welding temperature, with resultant burning and crystallization. In this process 100 per cent welds are the rule rather than the exception.

The production of pig iron in the United States last year amounted to 39,150,000 tons, according to *The Iron Age*, which is about 30 per cent in excess of the output for 1915. The production of steel in 1916 was probably in excess of 42,000,000 tons.

The Council of The Institution of Civil Engineers of Great Britain have extended an invitation to any members of The American Society of Mechanical Engineers who may be visitors in London to use The Institution Library and Reading Rooms, as well as to attend the meetings of The Institution, and have authorized the necessary steps to give effect to this on the presentation of an introduction from our Society. The Council trust that their American professional colleagues may often visit and make use of the new home of the Institution.

In the cooling of electrical machinery, with the high-speed units of large output, the designer is seriously handicapped. In a 15,000 kva. turbo-alternator, say, which is a medium size nowadays, the total loss is about 545 kw., and an enormous volume of cooling air is required for carrying away the heat due to this loss. According to Mr. B. G. Lamme, an expenditure of 1 kw. in 1 min. will raise the temperature of 100 cu. ft. of air 18 deg. cent. Therefore, for a temperature rise of the outgoing air of 20 deg. cent. above that of the incoming air a loss of 545 kw. will necessitate a supply of ventilating air of approximately 50,000 cu. ft. per min.—*The Electrician* (London), Feb. 2, 1917.

The endothermic energy of acetylene makes its ignition temperature low, thus preventing high compression in an engine cylinder. This in turn detracts from the efficiency of the engine and bars the economical use of this gas for power purposes. As compared with all other industrial substances acetylene occupies a position at the top of the list for light and heat. To get a substance which would compete with acetylene in its present field it would be necessary to get one with a higher endothermic energy content. Through well-known laws of chemistry it is recognized as impossible to obtain such a substance by any combination of carbon and hydrogen.—*The Engineer* (London), Feb. 23, 1917.

Mr. Max Toltz, member of the Council of the Am.Soc.M.E., recently introduced into the House of Representatives of the State of Minnesota a "bill for an act to provide for the safety of life and property in this state in the construction and use of steam boilers; creating a board of boiler rules to prescribe regulations for boilers used in this state, which will be uniform with other state rules now in existence, in order to provide for the free interchange of boilers between states; to define the power of the board of boiler rules; to provide penalties for the violation of this act and rules and regulations of the boiler rules."

The bill provides for the appointment of a board consisting of preferably a professor of mechanical engineering of the University of Minnesota, a manufacturer of boilers, a user of boilers, and a consulting engineer. The board is to formulate rules for the construction of steam boilers, as nearly as practicable in conformity with the A.S.M.E. Boiler Code.

JUNIOR AND STUDENT PRIZE PAPERS

ON the recommendation of the Am.Soc.M.E. Prize Committees, the Junior Prize for 1916 was awarded to L. B. McMillan for his paper entitled the Heat Insulating Properties of Commercial Steam Pipe Coverings. Honorable mention was awarded to Victor J. Azbe for his paper on Power Plant Efficiency, and Herbert B. Reynolds for his paper on the Flow of Air and Steam through Orifices.

Student Prizes for 1916 were awarded to: Boynton M. Green, Leland Stanford University, for his paper on Bearing Lubrication; Howard E. Stevens, Rensselaer Polytechnic Institute, for his paper on An Investigation of the Dynamic Pressure on Submerged Flat Plates, and M. Adam, Louisiana State University, for his paper on The Adaptability of the Internal-Combustion Engine to Sugar Factories and Estates.

Honorable Mention in the Student Prize Competition was awarded to: M. Boyd Gordon, University of Cincinnati, for his paper on A New Type of Uniflow Engine; S. C. Williams, Stevens Institute of Technology, for his paper on Photostatic Reproduction, and Charles P. Miller, Pennsylvania State College, for his paper on Investigation of Properties of Low- and Medium-Carbon Steels.

Abstracts of the papers awarded Junior Prizes have already appeared in The Journal and abstracts of the papers awarded Student Prizes are published below.

DYNAMIC PRESSURE OF SUBMERGED FLAT PLATES

By HOWARD E. STEVENS,[1] AUBURN, N. Y.

THE object of this investigation was to find an equation expressing the relation between the velocity of a stream and the resulting pressure on a submerged flat plate held perpendicular and at right angles to the direction of flow. Experiments were conducted with the plate at different depths below the surface in order to establish whether this affects the equation. The effect of varying the area and shape of the plate was determined, and one plate was used only partially submerged to ascertain whether the same equation would hold.

In all these experiments the plate was moved through still water. Now, there might be some question as to whether such results would apply to moving water impinging on a stationary plate. In the early part of the nineteenth century Duchemin found that results obtained by one method apply to the other. Such authorities as Lanchester, Zahm and See all agree that the cases are identical. However, De Villamil says they would be the same only when surrounding conditions are identical. Thus, results obtained by moving a body in still water would only apply to a stationary plate if the moving water were in a static condition; that is, if tank and water were moved as a whole. In refutation of this statement, it is very evident that the water impinges on the plate just the same whether the tank moves or not, and is in no more static condition with reference to the plate than if it were an open stream.

The plate was fastened to a vertical piece of sheet steel, *F*, Fig. 1, which was bolted to a wooden block *A*. *F* was placed in such a position that, as the apparatus was moved, the thin edge cut the water. The upper end of *A* was forked, one arm going on either side of a framework *G*. At point *H* in each arm was a horizontal pivot, thus allowing *A* to swing to a vertical plane. Fastened to *A* was a horizontal arm of steel *J*. A link *K* with a horizontal knife edge across the bottom moved along *J*, and the knife edge rested in *V*-shaped grooves cut in the under side of *J*. To *K* was fastened a vertical wire *C*, the upper end of which was attached to the platform of a pair of scales. A small wire *D* fastened to the arm of the scales moved over a scale *E* as the arm moved up and down. This was to determine when the scales were balanced, as it was so arranged that then *D* was opposite the middle line of *E*. The frame *G* was clamped on a four-wheeled car which could be pushed along a track over a flume about 100 ft. long and 5 ft. wide. The axis of the frame was made parallel to the track, and the plate was made vertical with a spirit level (when the scales were in the balanced position), so that the plate was perpendicular to the direction of motion.

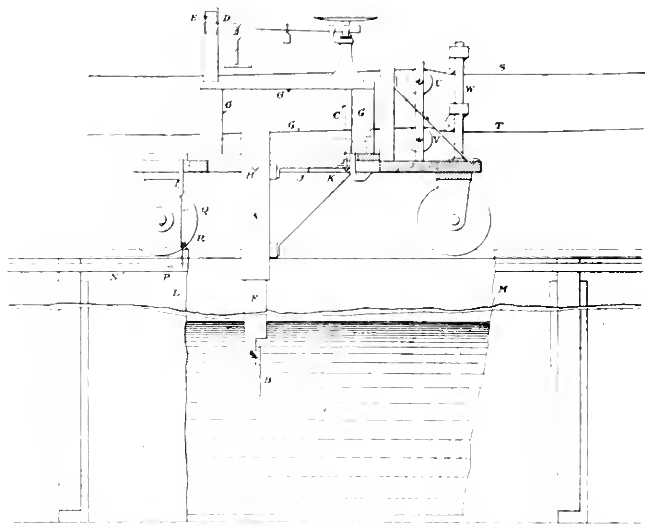

Fig. 1 Apparatus for Determination of Dynamic Pressure on Submerged Flat Plates

Fig. 1 shows a cross-section through the car and flume between points *L* and *M*, and an outside view to the left of *L* and to the right of *M*.

To determine the velocity a chronograph made by Wm. Gaertner and Co., of Chicago, was used. This had a revolving drum driven by clockwork to which a sheet of paper could be attached. Three pens which had a small lateral motion controlled by electromagnets made records on the paper as it moved. One pen recorded seconds. The electromagnet for this pen was connected in the circuit with a seconds pendulum on a clock. Every time the pendulum swung through its lowest point (once a second) a small needle on it passed through a bubble of mercury, closing the circuit. This excitation of the magnet pulled the pen sideways, giving little spines on the curve. A thin iron strip which ran along the side of the tank had little metal pins *P* every 8 ft., called "stations" in the following discussion. Attached to the car was an iron support *Q*, to which was fastened a flexible contact brush, *R*, which would rub on these pins. This would close the circuit through a second magnet and cause its pen to jump laterally. The third magnet was controlled by the experimenter, who

[1] Rensselaer Polytechnic Institute.

pushed the car. A horizontal handle was attached to the car with which to push it and on this handle was a push button. When the scales were balanced the experimenter closed the circuit through the third magnet by means of this push button, thus drawing the third pen sideways. In order to get a circuit while the car was moving, two trolley wires were used, S and T. Over these ran trolley wheels U and V, and other wheels on the standard W kept the wires pressed tightly against U and V, insuring a good contact. A wire connected U and V, and thus one circuit was made through W, P, R, Q, V, and T for the second magnet. The push button was connected by two wires to U and V, which thus gave a circuit for the third magnet.

Before making runs a plate was attached to F and the scales balanced to give the dead weight of the apparatus. Then weights were placed on the scales, the chronograph was started, and the car was pushed along at such a speed as to keep the scales balanced. Two runs were made with each weight. The weights used varied from 1 lb. to 40 lb., a sufficient range to give a good curve. One set of runs with various scale loads comprised a test. At the end of each test the plate was removed, a new dead weight found, and a series of runs made

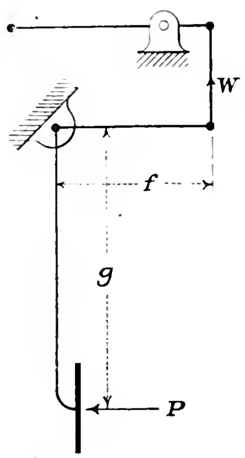

Fig. 2 Frame Diagram of Apparatus

in the same way with just the support of F to take the resistance of the water. These tests were called zero tests and gave the amount of pressure on the support. From these were plotted curves, scale readings vs. velocity. Log paper was used so that the curves would be straight lines and thus give a check.

First a 7-in. plate was used. The depth was varied by raising or lowering the level of the water in the flume. Then a round plate of one-half the area was used at three different depths. A rectangular plate 8 in. by 4 in. was tried with the long axis horizontal and then with it vertical, one test each way at a constant depth. A square plate 6 in. by 6 in. was next used at one depth only, and lastly the rectangular plate was used with the long axis vertical but only half submerged, giving virtually a square 4 in. by 4 in. below the surface. All the plates were painted. They were ⅛ in. thick.

Following is the method of computations. Three curves were obtained from the chronograph records: a, the seconds curve, the distance between two spines representing one second; b, the stations curve, each space between spines representing 8 ft. moved over by the car; c, the curve made by the pen controlled by the push button on the car. Where this is to the left, the scales were balanced, and only that part of the run (d to e) is of value for computations. The number of spaces on a between the spines nearest d and e was counted and the distance in inches measured. Dividing one by the other gave the seconds per inch of the curve. This was repeated with b, giving the stations per inch of the curve. Since each station represents 8 ft., multiplying the last result by 8 gave the feet per inch of curve b. Dividing this by the seconds per inch gave feet per second, or velocity. The weight on the scales was of course known and the dead weight was subtracted from it. Then the amount of pressure on the support at the known velocity was found. The difference between them gave the net weight on the scales corresponding to the pressure on the plate only. By knowing the lever arms f and g, P, Fig. 2, was computed; $Pg=fW$.

De Villamil says the desired equation is parabolic in form, therefore one was assumed:

$$P = KAV^n \dots\dots\dots\dots\dots\dots [1]$$

where P=total pressure on the plate in lb.
K=a coefficient
A=the area of the plate in square feet
V=the velocity in feet per second
n=a constant.

Dividing [1] by A, $P/A=KV^n$; passing to logs, $\log P/A = \log K + n \log V$, which is a straight-line formula.

P/A was computed for each run and $\log P/A$ was plotted as a function of $\log V$. Naturally these are straight lines; n is the tangent of the angle between a curve and the horizontal axis, while $\log K$ is the intercept on the vertical axis; n was found to be 2, while K had various values.

Then K was assumed to depend on the depth and the relation was taken as

$$K=b\,D^m \dots\dots\dots\dots\dots\dots [2]$$

where b = a coefficient
D = depth of center of plate below surface in feet
m = a constant.

Then $\log K = \log b + m \log D$, which is a straight line.

Log K was plotted vs. log D for each series (a series was composed of all the tests on one plate); m is the tangent of the angle between a curve and the horizontal axis and log b is the intercept on the vertical axis; m was found = —0.1, while b had various values. This in [2] gave $K = b/D^{0.1}$.

Then b was assumed to vary with the area. Two equations were assumed, $b = cA + g$, and $b = dA^f$. Several runs throughout the experiments were computed each way and the majority lay nearer the former curve than the latter, hence this was chosen: c was found to be 0.6, while g varied from 1.20 to 1.29, according to the shape of the piece. Since these are so nearly alike, it may be said that the shape of the plate is immaterial, and the average value of g = 1.25 will be taken.

$$\text{Now [1] is } P = KAV^2 \dots\dots\dots\dots [3]$$

Substituting for K its value,

$$P = AV^2 b\, D^{-0.1} \dots\dots\dots\dots [4]$$

Substituting for b its value,

$$P = AV^2/D^{0.1}(0.6A + 1.25) \dots\dots\dots [5]$$

which is the desired equation between the pressure and the velocity.

The investigation was carried a little further. Since P/A is the pressure in lb. per sq. ft., $1/W \times P/A$ (where W = weight of 1 cu. ft. of water) will be the pressure head h_p.

Since V is the velocity, $V^2/2g$ = the velocity head h_v. Now, from [1]

$$\frac{P}{A} = k_1$$

$$\text{then}\quad \frac{P}{A}\cdot\frac{1}{W} = \frac{k_1}{w}\cdot\frac{2g}{2g} = \frac{k_1 2g}{w}\times\frac{1}{2g}$$

$$h = \frac{k_1 2g}{w} = k_1 \frac{64.3}{62.4} = h_v\,.$$

$$\frac{h}{h_v} = 1.03\,k_1\,.$$

Substituting the values of k_1 found, this ratio varies from 1.31 to 1.67, with the average value of 1.47. Merriman says in his "Hydraulics" that it varies from 1.25 to 1.75, with best values from 1.4 to 1.5.

BEARING LUBRICATION

INFLUENCE OF SURFACE VELOCITY ON MEAN FILM THICKNESS

By BOYNTON M. GREEN, PITTSBURGH, PA.

Assuming that a machine will do the work for which it is designed, its economic value depends on the degree of efficiency with which it will do that work. The energy supplied to it is consumed in three ways: in overcoming the external load, or in doing the actual work required of the machine; in deforming the various parts of the machine, and in overcoming friction. The energy consumed in doing the actual work required is a legitimate expenditure for which there is value received. If the machine is properly designed, the energy lost in deforming its parts is returned somewhere during the work cycle, because the parts will never have been stressed beyond their elastic limit and hence, on returning to their original shape, will liberate the energy spent in deforming them, while that spent in accelerating masses will be given back upon their return to their original velocities. This leaves the energy lost in friction, which is a direct waste. Some friction is inevitable, so the question is: how may this loss be reduced to a minimum?

HISTORICAL DEVELOPMENT

It is interesting to note that this important problem of design was the last one to be attacked from a scientific standpoint. For years after the designer was able to calculate with a fair degree of accuracy the stresses in frames, shafts, levers and gears, he was content to design his bearings by guess and precedent. This tendency to slight bearing design was fostered by low machine speeds and lack of efficiency data. But with the introduction of electricity as a motive power and the resulting higher speeds and ever-increasing demand for greater efficiency, the necessity for better bearing design became urgent.

The first important attempt to investigate the conditions obtaining in a bearing was made in 1883 by Beauchamp Tower, an Englishman, at the request of the Institution of Mechanical Engineers. He used a journal 4 in. in diameter by 6 in. long, the bearing only covering the upper half of the journal. He was able first to explain the difference between partial or greasy lubrication and complete or flooded lubrication. Tower's results were qualitative rather than quantitative, but they brought out the facts that there was probably a complete film of oil separating journal and bearing in the case of flooded lubrication, and that the conditions of bearing friction in the case of flooded lubrication approximate fluid friction more nearly than solid friction.

The next step was made in 1885 by Prof. Osborne Reynolds, who used Tower's numerical data as the basis of a mathematical discussion of the subject. Reynolds applied a hydrodynamic theory to Tower's data and obtained an equation between the variation of pressure over the surface and journal velocity, which explained the existence of the oil film at a high pressure. He showed the presence of a wedging action of the lubricant, and this in turn brought out the importance of the bearing allowance, or difference in diameters of journal and bearing. From this followed the discovery of the general law for pressure distribution throughout the oil film, and the fact that the point of nearest approach of journal and bearing changes position with change of load. Reynolds realized that viscosity changes with temperature, so he made a determination of the relation between viscosity and temperature for olive oil, and deduced an empirical formula from which he obtained expressions for the approximate variation of viscosity with speed and load, since both these affect the bearing temperature. These expressions brought Tower's results into very close agreement with Reynolds' hydrodynamic theory. The hydrodynamic theory of fluid friction was also developed independently in 1884 by Petroff, a Russian, (data published in German in 1887).

This theory is undoubtedly the correct one to apply to the case of flooded lubrication. However, it cannot be applied directly, as the equations contain several constants which can only be determined by experiment, and it is to this work that later investigators have turned their attention rather than to the development of new theories. In 1903 some important investigations were carried on by O. Lasche for the Allgemeine Electricitäts-Gesellschaft of Berlin. Up to that time investigations had only been made with loads under 500 lb. per sq. in. and velocities under 500 r.p.m. (among the most important were those by Stribeck, Z.d.V.d.I. 1902), and the A.E.G. found it necessary to obtain data for velocities up to 3000 r.p.m. and correspondingly high loads. Lasche's work was quite exhaustive and incidentally threw considerable light on the transmission of heat away from the oil film.

FLUID FRICTION

The general equation for fluid friction is

$$\mu = \eta\, V/py$$

where μ = coefficient of friction
η = coefficient of viscosity
V = journal surface speed
p = pressure per unit of projected area of bearing
y = mean film thickness.

Usually p and V can be determined from the conditions of the problem and values of η can be taken from known data on oils. Concerning values of y, nothing definite is known, but some general deductions can be made. According to Smith and Marx's Machine Design, 1915, it is a function of the running-fit allowance, of p, of V, and of the temperature t of the bearing, which may be summed up in the following expression

$$y = \frac{k_a V^x}{p^w t^z}$$

From a consideration of this expression and its application in the general equation for friction it would seem that the

[1] Leland Stanford University.

next step would be an investigation of the mean thickness of oil film. Some work was done on this subject in 1897 by Professor Kingsbury (Jour. Am. Soc. Nav. Eng.), but as he used air as a lubricant, his results can only be taken as an indication of what to expect when using oil. As the mean film thickness y is influenced by four variables, it would be necessary to make the investigation in four steps. In Kingsbury's experiment the velocity only was changed. The pressure and allowance were kept constant while the apparatus was allowed to run until the temperature became constant before any test readings were taken.
